The positive Arctic ocean dynamic sea-level change is driven by increased freshwater input (Couldrey et al., 2020). The north-west Pacific dipole is driven by the intensification of the Kuroshio current in response to reduced heat loss and in some models to wind stress change (Chen et al., 2019a; Couldrey et al., 2020).

The North Atlantic sea-level change dipole is forced by a reduction in heat loss from the ocean north of 40ºN (i.e., net heat uptake), which in all Earth system models leads to a weakening of the AMOC, although the magnitude has a large model spread (Gregory et al., 2016; Huber and Zanna, 2017, Section 9.2.3.1). The reduced northward transport of warm, salty water (Section 9.2.2) causes further ocean dynamic sea-level change, whose details are model-dependent. North of 40ºN, this redistribution leads to a sea-level rise, predominantly halosteric, reinforcing the thermosteric effect of heat uptake (Couldrey et al., 2020). Comparison of observed Atlantic ocean heat content for 1955-2017 with a reconstruction assuming no change in circulation indicates that the thermosteric sea-level change resulting from southward redistribution of heat may be detectable (Zanna et al., 2019a). This redistribution causes a tendency for SST cooling north of 40ºN and anomalous heat input from the atmosphere, and thus a positive feedback on AMOC weakening (Winton et al., 2013; Gregory et al., 2016; Couldrey et al., 2020; Todd et al., 2020). Many climate and ocean models agree that the AMOC weakening is associated with pronounced thermosteric sea-level rise along the American coast around 40ºN (Figures 9.12, 9.26), leading to a relatively large ocean dynamic sea-level rise in this region (Yin, 2012; Bouttes et al., 2014; Slangen et al., 2014a; Little et al., 2019; Lyu et al., 2020a).

In summary, ocean dynamic sea-level change involves changes to temperature and salinity and responses of currents to changing forcing, with significant variability driven by unforced oceanic variability. Projections of dynamic sea-level variability require fully three-dimensional ocean models and only high-resolution ocean models are statistically consistent on short timescales with satellite altimeter observations (*very high confidence*).

9.3 Sea ice

9.3.1 Arctic Sea Ice

9.3.1.1 Arctic Sea-Ice Coverage

The observed decrease of Arctic sea-ice area is a key indicator of large-scale climate change (Section 2.3.2.1.1, Cross-Chapter Box 2.2). The SROCC (Meredith et al., 2019) assesses that sea-ice extent, which is the total area of all grid cells with at least 15% sea-ice concentration, has declined since 1979 in each month of the year (*very high confidence*). In contrast to the SROCC, we assess changes in sea-ice area (the actual area of the ocean covered by sea ice) rather than sea-ice extent, because sea-ice area is geophysically more relevant and not grid-dependent (Notz, 2014; Ivanova et al., 2016; Notz et al., 2016; Notz and SIMIP Community, 2020). Arctic sea-ice area is calculated based on measurements by passive microwave satellite sensors that provide near-continuous measurements of gridded, pan-Arctic sea-ice concentration from 1979 onwards. Irreducible uncertainties in the conversion of thermal microwave brightness temperature to sea-ice concentration and choices in algorithm design cause uncertainties in observed Arctic sea-ice area, which are, though, far smaller than the observed sea-ice loss (e.g., Comiso et al., 2017b; Niederdrenk and Notz, 2018; Alekseeva et al., 2019; Kern et al., 2019; Meier and Stewart, 2019). Sea-ice area has decreased from 1979 to the present in every month of the year (*very high confidence*, Figure 9.13). The absolute and the relative ice losses are highest in late summer-early autumn (*high confidence*, Figure 9.13). Averaged over the decade 2010-2019, monthly-average Arctic sea-ice area in August, September and October has been around 2

ACCEPTED VERSION SUBJECT TO FINAL EDITING

million km² (or about 25%) smaller than that during 1979-1988 (*high confidence*, Figure 9.13).

[START FIGURE 9.13 HERE]

Figure 9.13: Arctic sea-ice historical records and CMIP6 projections. Left: Absolute anomaly of monthly-mean Arctic sea-ice area during the period 1979 to 2019 relative to the average monthly-mean Arctic sea-ice area during the period 1979 to 2008. Right: Sea-ice concentration in the Arctic for March and September, which usually are the months of maximum and minimum sea-ice area, respectively. First column: Satellite-retrieved mean sea-ice concentration during the decade 1979-1988. Second column: Satellite-retrieved mean sea-ice concentration during the decade 2010-2019. Third column: Absolute change in sea-ice concentration between these two decades, with grid lines indicating non-significant differences. Fourth column: number of available CMIP6 models that simulate a mean sea-ice concentration above 15 % for the decade 2045-2054. The average observational record of sea-ice area is derived from the UHH sea-ice area product (Doerr et al., 2021), based on the average sea-ice concentration of OSISAF/CCI (OSI-450 for 1979-2015, OSI-430b for 2016-2019)(Lavergne et al., 2019), NASA Team (version 1, 1979-2019)(Cavalieri et al., 1996) and Bootstrap (version 3, 1979-2019)(Comiso, 2017) that is also used for the figure panels showing observed sea-ice concentration. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.13 HERE]

The SROCC discussed the regional distribution of Arctic sea-ice loss and their findings remain valid for the updated time series covering 2019 (Figure 9.13). Sea-ice loss in winter is strongest in the Barents Sea, while summer losses occur primarily at the summer sea-ice region margins, in particular in the East Siberian, Chukchi, Kara and Beaufort Seas (Frey et al., 2015; Chen et al., 2016; Onarheim et al., 2018; Peng and Meier, 2018; Maksym, 2019). In the Bering Sea, expanding winter sea-ice cover was observed until 2017 (Frey et al., 2015; Onarheim et al., 2018; Peng and Meier, 2018), but a marked reduction in sea-ice concentration has occurred since then (Stabeno and Bell, 2019)(*high confidence*).

With respect to seasonal changes in the sea-ice cover, the winter sea-ice loss causes a decrease in the average sea-ice age and fraction of multi-year ice as assessed by the SROCC (*very high confidence*), and also of the ocean area covered intermittently by sea ice (Bliss et al., 2019). In contrast, the seasonal ice zone (covered by sea ice in winter but not in summer) has expanded regionally (Bliss et al., 2019) and over the whole Arctic (Steele and Ermold, 2015), because the loss of summer sea-ice area is larger than the loss of winter sea-ice area. Arctic sea ice retreat includes an earlier onset of surface melt in spring and a later freeze up in fall, lengthening the open-water season in the seasonal sea-ice zone (Stroeve and Notz, 2018). However, there is *low agreement* in quantification of regional trends of melt and freeze onset between different observational products (Bliss et al., 2017; Smith and Jahn, 2019).

Reconstructions of Arctic sea-ice coverage put the satellite period changes into centennial context. Direct observational data coverage (Walsh et al., 2017) and model reconstructions (Brennan et al., 2020) warrant *high confidence* that the low Arctic sea-ice area of summer 2012 is unprecedented since 1850, and that the summer sea-ice loss is significant in all Arctic regions except for the Central Arctic (Cai et al., 2021). Direct wintertime observational data coverage before 1953 is too sparse to reliably assess Arctic sea-ice area. Since 1953, the years 2015 to 2018 had the four lowest values of maximum Arctic sea-ice area, which usually occurs in March (Figure 2.20) (*high confidence*). Reconstructions of Arctic sea-ice area before 1850 remain sparse, and as in the SROCC, there remains *medium confidence* that the current sea-ice levels in late summer are unique during the past 1 kyr (Kinnard et al., 2011; De Vernal et al., 2013b). (Section 2.3.2.1.1)

The observed fluctuations and trends of the Arctic sea-ice cover arise from a combination of changes in natural external forcing and anthropogenic forcing, internal variability and internal feedbacks (e.g., Notz and Stroeve, 2018; Halloran et al., 2020). New paleo-proxy techniques indicate regional sea-ice changes over epochs and millennia and allow possible drivers to be assessed. Biomarker IP25 (Belt et al., 2007) together with other sedimentary biomarkers (Belt, 2018) provides local temporal information on seasonal sea-ice

ACCEPTED VERSION SUBJECT TO FINAL EDITING

coverage, permanent sea-ice coverage and ice-free waters with occasional ambiguous contrasting results (Belt, 2019). These records and other proposed paleo proxies including bromine in ice cores (Spolaor et al., 2016), dinocyst assemblages (e.g., De Vernal et al., 2013b) and driftwood (e.g., Funder et al., 2011) provide evidence of sea-ice fluctuations that exceed internal variability (*high confidence*).

The inferred sea-ice fluctuations over millennia can be related to Northern-hemisphere temperature evolution and give rise to Arctic-wide fluctuations in sea-ice coverage in the paleo record (Section 2.3.2.1.1). On a regional scale, fluctuations include decreased sea-ice cover during the Allerød warm period (14.7-12.9 ka) in the Laptev (Hörner et al., 2016) and Bering Sea (Méheust et al., 2018); an extensive sea-ice cover during the Younger Dryas (~12 ka) in the Bering (Méheust et al., 2018), Kara (Hörner et al., 2018), Laptev (Hörner et al., 2016) and Barents (Belt et al., 2015) Seas and at the Yermak Plateau (Kremer et al., 2018); little sea ice during the early Holocene, when Northern hemisphere summer insolation was higher than today (8000 to 9000 years before present), in the North Icelandic Shelf area (Cabedo-Sanz et al., 2016; Xiao et al., 2017), Sea of Okhotsk (Lo et al., 2018), Canadian Arctic (Spolaor et al., 2016), Barents (Berben et al., 2017), Bering (Méheust et al., 2018), and Chukchi (Stein et al., 2017) Seas, at the Yermak Plateau (Kremer et al., 2018) and north of Greenland (Funder et al., 2011); increasing sea-ice cover throughout much of the middle and late Holocene around Svalbard (Knies et al., 2017), in the North Icelandic Shelf area (Cabedo-Sanz et al., 2016; Harning et al., 2019; Halloran et al., 2020), north of Greenland (Funder et al., 2011), and in the Western Greenland (Kolling et al., 2018), Barents (Belt et al., 2015; Berben et al., 2017), Chukchi (De Vernal et al., 2013a; Stein et al., 2017) and Laptev (Hörner et al., 2016) Seas. The consistent, Arctic-wide changes give *high confidence* in millennial-scale co-variability of the sea-ice cover with temperature fluctuation.

The SROCC assessed that approximately half of the satellite-observed Arctic summer sea ice loss is driven by increased concentrations of atmospheric greenhouse gases (*medium confidence*). Recent attribution studies now allow the strengthened assessment that it is *very likely* that more than half of the observed Arctic sea-ice loss in summer is anthropogenic (Section 3.4.1.1). This assessment is confirmed by process-based analyses of Arctic sea-ice loss not assessed by the SROCC. Similar to the paleo record, the satellite record of Arctic sea-ice area from 1979 onwards is strongly linearly correlated with global mean temperature on decadal and longer time scales (Figure 9.14a,e) (e.g., Gregory et al., 2002; Rosenblum and Eisenman, 2017) . The correlation holds across all months with R^2 ranging from 0.61 to 0.81 (Niederdrenk and Notz, 2018). However, in contrast to paleo-records, sea-ice fluctuations during the satellite period are only weakly correlated with Northern Hemisphere insolation (Notz and Marotzke, 2012); modern Northern Hemisphere sea-ice area is more strongly correlated with atmospheric CO_2 concentration (Johannessen, 2008; Notz and Marotzke, 2012) and cumulative anthropogenic CO_2 emissions (Figure 9.14b,f) (Zickfeld et al., 2012; Herrington and Zickfeld, 2014; Notz and Stroeve, 2016). R^2 values of the correlation between sea-ice area and cumulative CO_2 emissions range across all months from 0.76 to 0.92 (Stroeve and Notz, 2018). In summary, there is *high confidence* that satellite-observed Arctic sea-ice area is strongly correlated with global mean temperature, CO_2 concentration and cumulative anthropogenic CO_2 emissions.

In addition to changes in the external forcing, internal variability substantially affects Arctic sea ice, evidenced from both paleo records (e.g., (Chan et al., 2017; Hörner et al., 2017; Kolling et al., 2018)) and satellites after 1979 (e.g., Notz and Stroeve, 2018; Roberts et al., 2020) (*high confidence*). Most of the internal variability on annual time scales is related to atmospheric temperature fluctuations, for example linked to cyclone activities (Wernli and Papritz, 2018; Olonscheck et al., 2019), while multidecadal internal variability is primarily related to changes in oceanic heat transport (Zhang, 2015; Halloran et al., 2020). These mechanisms are represented in current climate models (Olonscheck et al., 2019; Halloran et al., 2020), but the resulting internal variability of September sea-ice area in CMIP5 and CMIP6 models, as given by the ensemble mean standard deviation $s_{SIA,Sep}$=0.5 million km² (Olonscheck and Notz, 2017; Notz and SIMIP Community, 2020), exceeds the estimated internal variability for the period 1850 to 1979 from both reanalyses ($s_{SIA,Sep}$ =0.3 million km^2) and direct observational reconstructions ($s_{SIA,Sep}$ =0.2 million km^2) (Brennan et al., 2020) (*medium confidence* because of limited reliability of longer-term sea-ice reconstructions). Internal variability has been estimated to have contributed 30 to 50% of the observed Arctic summer sea-ice loss since 1979 (Kay et al., 2011; Stroeve et al., 2012; Ding et al., 2017, 2019; England et al., 2019). However, this estimate from models might be biased towards internal over forced variability

ACCEPTED VERSION SUBJECT TO FINAL EDITING

because of the models' high internal variability and because the CMIP5 simulated September sea-ice sensitivity to forcing is lower than observed, even if internal variability is taken into account (Notz and Stroeve, 2016; Rosenblum and Eisenman, 2017). Most CMIP6 models fail to simulate the observed sensitivity of sea-ice loss to CO_2 emissions (as a proxy for time) and to temperature simultaneously. However, they better capture the observed sensitivity of sea-ice loss to CO_2 emissions than CMIP5 models (Section 3.4.1, Figure 9.14h; (Notz and SIMIP Community, 2020)).

The SROCC examined the different atmospheric and oceanic processes that caused the observed sea-ice loss, with recent studies providing new evidence for the importance of variations in air temperature (Olonscheck et al., 2019; Dahlke et al., 2020), wind patterns (Graham et al., 2019), oceanic heat flux (Docquier et al., 2021) and riverine heat influx (Park et al., 2020). As in the SROCC, the relative contribution of each physical cause to the sea-ice loss cannot be robustly quantified because of disagreement among models (Burgard and Notz, 2017), sparse observations and limited understanding of the variation of each factor with global mean temperature. This is addressed by new diagnostics available from CMIP6 simulations, which now allow for more detailed analyses of the drivers of sea-ice loss at a process level (Keen et al., 2021).

In examining temperature thresholds for the loss of Arctic summer sea ice, the SR1.5 (Hoegh-Guldberg et al., 2018) and the SROCC assess that a reduction of September-mean sea-ice area to below 1 million km^2, practically a sea-ice-free Arctic Ocean, is more probable for a global mean warming of 2°C compared to global mean warming of 1.5°C (*high confidence*). Analyses of CMIP6 simulations (Notz and SIMIP Community, 2020) confirm this result, as they show that on decadal and longer time scales, Arctic summer sea ice area will remain highly correlated with global mean temperature until the summer sea ice has vanished (Figure 9.14a,e). Quantitatively, existing studies (Screen and Williamson, 2017; Jahn, 2018; Ridley and Blockley, 2018; Sigmond et al., 2018; Notz and SIMIP Community, 2020) additionally show that for a warming between 1.5 and 2 ˚C, the Arctic will only be practically sea-ice free in September in some years, while at 3 ˚C warming the Arctic is practically sea-ice free in September in most years, with longer practically sea-ice-free periods at higher warming levels (*medium confidence*). However, because of the CMIP5 and CMIP6 models' generally too low sensitivity of sea-ice loss to global warming, there is only *low confidence* regarding the specific warming level at which the Arctic Ocean first becomes practically sea-ice free (Notz and SIMIP Community, 2020). (Section 4.3.2.1)

[START FIGURE 9.14 HERE]

Figure 9.14: Monthly mean March (a-d) and September (e-h) sea-ice area as a function of global surface air temperature (GSAT) anomaly (a,e); cumulative anthropogenic CO_2 emissions (b,f); year (c,g) in CMIP6 model simulations (shading, ensemble mean as bold line) and in observations (black dots). Panels d and h show the sensitivity of sea-ice loss to anthropogenic CO_2 emissions as a function of the modelled sensitivity of GSAT to anthropogenic CO_2 emissions. In panels d and h, the black dot denotes the observed sensitivity, while the shading around it denotes internal variability as inferred from CMIP6 simulations (after Notz and SIMIP Community, 2020). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.14 HERE]

In contrast, CMIP6 models capture the observed sensitivity of Arctic sea ice area to cumulative anthropogenic CO_2 emissions well, providing *high confidence* that the Arctic Ocean will *likely* become practically sea-ice free in the September mean for the first time for future CO_2 emissions of less than 1000 Gt and before the year 2050 in all SSP scenarios (Notz and SIMIP Community, 2020). This new assessment is consistent with an observation-based projection of a practically sea-ice free Arctic Ocean in September for additional anthropogenic CO_2 emissions of 800± 330 $GtCO_2$ beyond the year 2018 (Notz and Stroeve, 2018; Stroeve and Notz, 2018). This estimate may, however, be too high due to neglecting possible future reduction in atmospheric aerosol load that would cause additional warming (Gagné et al., 2015a; Wang et al., 2018) and is subject to the same constraints as the carbon budget analysis for global mean temperature (see section 5.5 for details). Based on CMIP6 simulations, it is *very likely* that the Arctic Ocean will remain sea-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ice covered in winter in all scenarios throughout this century (Sections 4.3.2, 4.4.2).

There is indication that CMIP6 simulations of Arctic sea ice have improved relative to CMIP5 (Section 3.4.1.1), but detailed evaluation studies exist mainly for CMIP5 models. These studies found that CMIP5 model projections and reanalyses show a large spread of simulated regional Arctic sea-ice concentration (Laliberté et al., 2016; Chevallier et al., 2017), which remains true for CMIP6 models (Shu et al., 2020; Wei et al., 2020). In addition, both CMIP5 and CMIP6 models show a large spread in the simulated seasonal cycle of Arctic sea-ice area, with too high a sea-ice area in March in the ensemble mean (Notz and SIMIP Community, 2020). CMIP5 models also have been found to have difficulty simulating realistic landfast sea ice (Laliberté et al., 2018). These findings imply that both CMIP5 and CMIP6 models do not realistically capture the regional and seasonal processes governing observed Arctic sea-ice evolution, causing *low confidence* in the models' projections of future regional sea-ice evolution, including updated projections for shipping routes across the Northern Sea Route and Northwest Passage (Wei et al., 2020).

CMIP5 models also have issues with capturing the seasonal cycle of observed changes in Arctic sea-ice drift speed, which affects their simulation of regional sea-ice concentration patterns. Direct measurements of Arctic sea ice from drift buoys and satellites show that drift speed of Arctic sea ice has increased over the satellite period in all seasons (e.g., Rampal et al., 2009; Docquier et al., 2017). In summer, CMIP5 models show a slowdown of Arctic sea-ice drift rather than the observed acceleration (Tandon et al., 2018). In winter, CMIP5 models generally capture the observed acceleration of Arctic drift speed. The drift acceleration is primarily caused by the decrease in concentration and thickness, both in the observational record (Rampal et al., 2009; Spreen et al., 2011; Olason and Notz, 2014; Docquier et al., 2017) and, for winter, in CMIP5 models (Tandon et al., 2018). Changes in wind speed are less important for the observed large-scale changes (Spreen et al., 2011; Vihma et al., 2012; Olason and Notz, 2014; Docquier et al., 2017; Tandon et al., 2018). In summary, there is *high confidence* that Arctic sea-ice drift has accelerated because of the decrease in sea ice concentration and thickness.

The SR1.5 assessed with *high confidence* that there is no hysteresis in the loss of Arctic summer sea ice. In addition, there is no tipping point or critical threshold in global mean temperature beyond which the loss of summer sea ice becomes self-accelerating and irreversible (*high confidence*). This is because stabilizing feedbacks during winter related to increased heat loss through thin ice and thin snow, and increased emission of longwave radiation from open water, dominate over the amplifying ice-albedo feedback (e.g., Eisenman, 2012; Wagner and Eisenman, 2015; Notz and Stroeve, 2018) (see section 7.4.2 for details on the individual feedbacks). Observed and modelled Arctic summer sea ice and global mean temperature are linked with little temporal delay, and the summer sea-ice loss is reversible on decadal time scales (Armour et al., 2011; Ridley et al., 2012; Li et al., 2013; Jahn, 2018). The loss of winter sea ice is reversible as well, but the loss of winter sea-ice area per degree of warming in CMIP5 and CMIP6 projections increases as the ice retreats from the continental shore lines, because these limit the possible areal fluctuations (e.g., Bathiany et al., 2016, 2020; Meccia et al., 2020) (*high confidence*) (Section 4.3.2.1).

9.3.1.2 Arctic Sea-Ice volume and thickness

The SROCC assessed with *very high confidence* that Arctic sea ice has become thinner over the satellite period from 1979 onwards, and this assessment is confirmed for the updated time series (section 2.3.2.1.1). Sea-ice area has also decreased substantially over this period (section 9.3.1.1), leading to the assessment that Arctic sea-ice volume has also decreased with *very high confidence* over the satellite period since 1979. There is, however, only *low confidence* in quantitative estimates of the sea-ice volume loss over this period because of a lack of reliable, long-term, pan-Arctic observations and substantial spread in available reanalyses (Chevallier et al., 2017). Current best estimates from reanalyses suggest a reduction of September Arctic sea ice volume of 55 to 65 % over the period 1979 to 2010, and of about 72 % over the period 1979 to 2016, with the latter deemed a conservative estimate (Schweiger et al., 2019).

For the more recent past, ice-thickness can be directly estimated from satellite estimates of sea-ice freeboard (Kwok and Cunningham, 2015; Kwok, 2018). Based on these retrievals, there is *medium confidence* that

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Arctic sea-ice volume has decreased since 2003. There is *low confidence* in the amount of decrease over this period and over the CryoSat-2 period from 2011 onwards primarily because of snow-induced uncertainties in the retrieval algorithms, the shortness of the record, and the small identified trend (e.g., (Bunzel et al., 2018; Petty et al., 2018, 2020)).

Observations of regional changes in sea-ice thickness vary in quality. Analysis of submarine data in the central Arctic Ocean suggests that sea ice there has thinned by about 75 cm compared to the mid-1970s (Section 2.3.2.1.1). For smaller regions, data are too sparse to allow for quantitative estimates of long-term trends (King et al., 2017; Rösel et al., 2018), but a clear thinning signal over 10 to 20 years has been found for sea ice in Fram Strait (Spreen et al., 2020), north of Canada (Haas et al., 2017) and for landfast ice in Kongsfjorden/Svalbard (Pavlova et al., 2019). CMIP5 models and reanalyses fail to capture the observed distribution (Stroeve et al., 2014; Shu et al., 2015) and evolution (Chevallier et al., 2017) of Arctic sea-ice thickness. Most CMIP6 models do not capture the observed spatial distribution of sea-ice thickness realistically (Wei et al., 2020). This leads to *low confidence* in estimates of thickness from reanalyses and from CMIP5 and CMIP6 models, and in these models' projections of sea-ice volume.

9.3.2 Antarctic Sea Ice

9.3.2.1 Antarctic sea-ice coverage

The SROCC (Meredith et al., 2019) assessed that there was no significant trend in annual mean Antarctic sea-ice area over the period of reliable satellite retrievals starting in 1979 *(high confidence)*. The updated time series is consistent with this assessment. It includes a maximum sea-ice area in 2014, a substantial decline from then until the minimum sea-ice area in 2017, and an increase in sea-ice area since then (Schlosser et al., 2018; Maksym, 2019; Parkinson, 2019) (Figure 9.15, Figure 2.20). As assessed in Section 2.3.2.1.2, the possible significance of the increase in mean Antarctic sea-ice area over the shorter period 1979 to 2014 (Figure 2.20) (Simmonds, 2015; Comiso et al., 2017a) is unclear. This is because of observational uncertainty (see section 9.3.1.1), large year-to-year fluctuations in all months (Figure 9.15), and limited understanding of the processes and reliability of year-to-year correlation of Antarctic sea-ice area (Yuan et al., 2017).

As assessed by the SROCC, the evolution of mean Antarctic sea-ice area is the result of opposing regional trends (*high confidence*), with slightly decreasing sea-ice cover during the period 1979 to 2019 in the Amundsen Sea and the Bellingshausen Sea, particularly during summer, and slightly increasing sea-ice cover in the eastern parts of the Weddell Sea and the Ross Sea (Figure 9.15). With the exception of the Ross Sea, these trends are not significant considering the large variability of the time series (Yuan et al., 2017).

The SROCC assessed that the regional trends are closely related to meridional wind trends (*high confidence*). This is the case as the regional trends in the maximum northward extent of the ice cover (Figure 9.15) are determined by the balance between the northward advection of the ice that is formed in polynyas near the continental margin, and the lateral and subsurface melting through oceanic heat fluxes. The advection of the sea ice is strongly correlated with winds and cyclones (Schemm, 2018; Vichi et al., 2019; Alberello et al., 2020). Accordingly, the increasing sea-ice area in the Ross Sea can be linked to a strengthening of the Amundsen Sea low (e.g., (Holland et al., 2017b, 2018)), while other regional sea-ice trends in the austral fall can be linked to changes in westerly winds, cyclone activity and the Southern Annular Mode (SAM) in summer and spring (Doddridge and Marshall, 2017; Holland et al., 2017a; Schemm, 2018). In addition to the wind-driven changes, increased near-surface ocean stratification (Section 9.2.1.3) has contributed to the observed increase in sea-ice coverage (e.g., (Purich et al., 2018; Zhang et al., 2019b)) as it tends to cool the surface ocean (Sections 9.2.1.1, 9.2.3.2). The changes in stratification result partly from surface freshening (De Lavergne et al., 2014) (associated with increased northward sea-ice advection (Haumann et al., 2020) and/or melting of the Antarctic ice sheet (e.g., (Haumann et al., 2020; Jeong et al., 2020; Mackie et al., 2020)) (*medium confidence*)) and are amplified by local ice-ocean feedbacks (Goosse and Zunz, 2014; Lecomte et al., 2017; Goosse et al., 2018). In the Amundsen Sea, strong ice-shelf melting can cause local sea-ice melt next to the ice-shelf front by entraining warm Circumpolar Deep Water to the ice-shelf cavity

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and surface ocean (*medium confidence*) (Sections 9.2.3.2, 9.4.2.2) (Jourdain et al., 2017; Merino et al., 2018). It has also been suggested that the observed regional increase in sea ice coverage since 1979 results from a long-term Southern Ocean surface cooling trend (e.g., (Kusahara et al., 2019; Jeong et al., 2020)) but the importance of this mechanism for the observed sea-ice evolution is unclear owing to intricate feedbacks between sea-ice change and surface cooling (Haumann et al., 2020). The importance of changing wave activity (Section 9.6.4.2; Kohout et al., 2014; Bennetts et al., 2017; Roach et al., 2018b) on sea ice is unclear due to limited process understanding. In summary, there is *high confidence* that regional Antarctic trends are primarily caused by changes in sea-ice drift and decay, with *medium confidence* in a dominating role of changing wind pattern. The precise relative contribution of individual drivers remains uncertain because of limited observations, disagreement between models, unresolved processes, and temporal and spatial remote linkages caused by sea-ice drift (Section 9.2.3.2, (Pope et al., 2017)).

Recent research has confirmed the SROCC assessment of atmospheric and oceanic drivers of the sea-ice decline from 2014 to 2017, which can be linked to changes in both subsurface ocean heat flux (Meehl et al., 2019; Purich and England, 2019) and atmospheric circulation, with the latter partly related to teleconnections with the tropics (Meehl et al., 2019; Purich and England, 2019; Wang et al., 2019a). In the Weddell Sea, these changes caused in 2017 the re-emergence of the largest polynya over the Maud Rise since the 1970s (Campbell et al., 2019; Jena et al., 2019; Turner et al., 2020) (Section 9.2.3.2).

[START FIGURE 9.15 HERE]

Figure 9.15: Antarctic sea-ice historical records and CMIP6 projections. Left: Absolute anomaly of observed monthly-mean Antarctic sea-ice area during the period 1979 to 2019 relative to the average monthly-mean Antarctic sea-ice area during the period 1979 to 2008. Right: Sea-ice coverage in the Antarctic as given by the average of the three most widely used satellite-based estimates for September and February, which usually are the months of maximum and minimum sea-ice coverage, respectively. First column: Mean sea-ice coverage during the decade 1979-1988. Second column: Mean sea-ice coverage during the decade 2010-2019. Third column: Absolute change in sea-ice concentration between these two decades, with grid lines indicating non-significant differences. Fourth column: number of available CMIP6 models that simulate a mean sea-ice concentration above 15 % for the decade 2045-2054. The average observational record of sea-ice area is derived from the UHH sea-ice area product (Doerr et al., 2021), based on the average sea-ice concentration of OSISAF/CCI (OSI-450 for 1979-2015, OSI-430b for 2016-2019)(Lavergne et al., 2019), NASA Team (version 1, 1979-2019)(Cavalieri et al., 1996) and Bootstrap (version 3, 1979-2019)(Comiso, 2017) that is also used for the figure panels showing observed sea-ice concentration. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.15 HERE]

The AR5 (Collins et al., 2013) and the SROCC found *low confidence* in future projections of Antarctic sea ice. This includes the projected mitigation of the sea-ice loss by stratospheric ozone recovery (Smith et al., 2012) and by an increased freshwater input from melting of the Antarctic ice sheet (Bronselaer et al., 2018). Compared to the interannual variability during the satellite record from 1979 onwards, models simulate too much variability both in CMIP5 (Zunz et al., 2013) and in CMIP6 (Roach et al., 2020). The seasonal cycle in sea-ice coverage is misrepresented in most CMIP5 (e.g., (Holmes et al., 2019)) and CMIP6 models (Roach et al., 2020), but the multi-model mean seasonal cycle in CMIP5 and CMIP6 agrees well with observations (Shu et al., 2015; Roach et al., 2020). Most CMIP5 models do not realistically simulate the evolution of Antarctic sea-ice volume (Shu et al., 2015) and consistently overestimate the amount of low concentration sea ice and underestimate the amount of high concentration sea ice (Roach et al., 2018a). CMIP6 models, in contrast, simulate a more realistic distribution of regional sea-ice coverage (Roach et al., 2020). Most CMIP5 models poorly represent Antarctic sea-ice drift (e.g., (Schroeter et al., 2018; Holmes et al., 2019)), affecting simulated historical trends, with models that simulate a strong sea-ice motion showing more variability in sea-ice coverage than models with weaker sea-ice motion (Schroeter et al., 2018). Owing to *limited agreement* between model simulations and observations, limited reliable observations on a process level and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

a lack of process understanding of the substantial spread in CMIP5 and CMIP6 model simulations, there remains *low confidence* in existing future projections of Antarctic sea-ice evolution.

The discrepancy between the modelled and observed evolution of Antarctic sea ice has been related by the SROCC to deficiencies in stratification, freshening by ice shelf melt water, clouds, and other wind and ocean driven processes. Recent studies highlight the possible mis-representation of freshwater fluxes from ice shelves (Jeong et al., 2020), and the possible effect of the low resolution of most models (Sidorenko et al., 2019), even though lower-resolution models are in principle capable of a realistic simulation of the seasonal sea-ice budgets in the Southern Ocean (Holmes et al., 2019). The relative importance of these possible reasons for model-shortcomings remains unclear (see section 3.4.1.2 for details).

The analysis and understanding of the long-term evolution of the Antarctic sea-ice cover is hindered by the scarcity of observational records before the satellite period and the scarcity of paleo records (see section 2.3.2.1.2 for further details). Such long records are particularly relevant given that the Southern Ocean response to external forcing takes longer than the length of the available direct observational record (Goosse and Renssen, 2001; Armour et al., 2016). There is only *limited evidence* for large-scale decadal fluctuations in sea-ice coverage caused by large-scale temperature and wind forcing. Sparse direct pre-satellite observations suggest a decrease in sea-ice coverage from the 1950s to the 1970s (Fan et al., 2014). Paleo-proxy data indicate that, on multi-decadal to multi-centennial time scales, sea-ice coverage of the Southern Ocean follows large-scale temperature trends (e.g., (Crosta et al., 2018; Chadwick et al., 2020; Lamping et al., 2020)), for example linked to fluctuations in the El Niño Southern Oscillation and Southern Annular Mode (Crosta et al., 2021), and that during the Last Glacial Maximum Antarctic sea ice extended to about the polar front latitude in most regions during winter, whereas the extent during summer is less well understood (e.g., (Benz et al., 2016; Xiao et al., 2016; Nair et al., 2019)).

Regionally, proxy data from ice cores consistently indicate that the increase of sea-ice area in the Ross Sea and the decrease of sea-ice area in the Bellingshausen Sea are part of longer centennial trends and exceed internal variability on multi-decadal time-scales (e.g., (Thomas et al., 2019; Tesi et al., 2020)) (*medium confidence*). These centennial trends are consistent with simulations from CMIP5 models (Hobbs et al., 2016a; Jones et al., 2016b; Kimura et al., 2017).

There is *low confidence* in the attribution of the observed changes in Antarctic sea-ice area (Section 3.4.1.2). Based on the available evidence, the lack of a negative trend of Antarctic sea-ice area despite substantial global warming in recent decades has been attributed to internal variability in analyses of the observational record (Meier et al., 2013; Gallaher et al., 2014; Gagné et al., 2015b), reconstructions from early observations (Fan et al., 2014; Edinburgh and Day, 2016) and proxy data (Hobbs et al., 2016a), and model simulations (Turner et al., 2013; Zunz et al., 2013; Zhang et al., 2019c). Nonetheless, without accurate simulations of observed changes, the possible contribution of anthropogenic forcing to the regional changes in sea-ice area remains unclear (Hosking et al., 2013; Turner et al., 2013; Haumann et al., 2014; Zhang et al., 2019c)

The attribution of the observed trends in atmospheric and oceanic forcing is also uncertain because of limited observational records and discrepancies between modelled and observed evolution of the sea-ice cover. More specifically, there is contrasting evidence for a direct role of stratospheric ozone depletion on the observed changes in atmospheric circulation (Haumann et al., 2014; England et al., 2016; Landrum et al., 2017). In contrast, there is *high confidence* that multi-decadal variations in the tropical Pacific and in the Atlantic affect the Amundsen Sea low (Li et al., 2014; Kwok et al., 2016; Meehl et al., 2016; Purich et al., 2016; Simpkins et al., 2016), while other modes of climate variability (Annex IV) affect, for example, Southern Ocean cyclone activity (Simpkins et al., 2012; Cerrone et al., 2017; Schemm, 2018).

9.3.2.2 Antarctic sea-ice thickness

The SROCC assessed that observations are too sparse to reliably estimate long-term trends in Antarctic sea-ice thickness. This remains true, and only qualitative statements on prevailing thicknesses are possible. Data

ACCEPTED VERSION SUBJECT TO FINAL EDITING

from ICESat-1 laser altimetry (Kurtz and Markus, 2012), from Operation IceBridge (Kwok and Kacimi, 2018), and long-term ship-board observations collected in the ASPeCt data set (Worby et al., 2008) suggest that sea ice thicker than 1 m prevails in regions of multi-year ice along the eastern coast of the Antarctic Peninsula in the Weddell Sea, in the high-latitude embayment of the Weddell Sea, and along the coast of the Amundsen Sea, with remaining regions dominated by thinner first year sea ice (*high confidence*). Regional patterns in ice thickness are affected by large snow deposition and resulting snow-ice formation (Massom et al., 2001; Maksym and Markus, 2008), and deformation, ridging, and rafting that regionally cause formation of very thick sea ice (Massom et al., 2006; Williams et al., 2015a). In addition, near ice shelves a sub-ice platelet layer from supercooled water can significantly increase sea-ice thickness (Hoppmann et al., 2020; Haas et al., 2021). Regarding snow thickness, observations are too sparse in space and time to reliably estimate changes across Southern Ocean sea ice (Webster et al., 2018).

There is *low confidence* in the long-term trend of Antarctic sea-ice thickness. Both ASPeCt and ICESat-1 measurements are biased low in regions with thick ice (Kern and Spreen, 2015), compared to results from reanalyses (Massonnet et al., 2013; Haumann et al., 2016) and observations with autonomous vehicles under sea ice (Williams et al., 2015a). Estimates of sea-ice thickness from Cryosat-2 do not substantially reduce uncertainty, primarily because of the unknown snow thickness and radar scattering above the snow–ice interface (Bunzel et al., 2018; Kwok and Kacimi, 2018; Kacimi and Kwok, 2020). Isolated in-situ time series show no clear long-term trend in landfast ice thickness in the Weddell Sea (Arndt et al., 2020). Reanalyses suggest overall increasing sea-ice thickness and volume between 1980 and 2010 (Holland et al., 2014; Zhang, 2014; Massonnet et al., 2015), while CMIP5 (Shu et al., 2015; Schroeter et al., 2018) and CMIP6 models simulate a decrease in Antarctic sea-ice volume over the historical period. Because of this discrepancy, and the unclear reliability of the reanalyses (Uotila et al., 2019), there is *low confidence* in CMIP5 and CMIP6 simulated future Antarctic sea-ice thickness.

9.4 Ice Sheets

9.4.1 Greenland Ice Sheet

9.4.1.1 Recent observed changes

In this section we present regional mass change time series for the Greenland Ice Sheet and assess the different processes causing the increase in mass loss. The vast increase in observational products from various platforms (e.g, GRACE, PROMICE, ESA-CCI, NASA MEaSUREs) provide a consistent and clear picture of a shrinking Greenland Ice Sheet (Colgan et al., 2019; Mottram et al., 2019; Mouginot et al., 2019; King et al., 2020; Mankoff et al., 2020; Moon et al., 2020; Sasgen et al., 2020; The IMBIE Team, 2020; Velicogna et al., 2020). Section 2.3.2.4.1 provides an updated estimate of the total Greenland Ice Sheet mass change in a global context (Figure 2.24). A paleo perspective on Greenland Ice Sheet evolution is presented in Section 9.6.2 with estimated ice sheet extent at different times shown in Figure 9.17.

For the 20th century, the SROCC (Meredith et al., 2019) presented one reconstruction for 1900-1983 and estimated mass change for the Greenland Ice Sheet and its peripheral glaciers for the period 1901-1990. Since the SROCC, a comprehensive new study has extended the satellite record back to 1972 (Mouginot et al., 2019,Figure 9.16). The rate of change of ice sheet mass was positive (i.e., it gained mass) in 1972-1980 (47±21 Gt yr^{-1}) and then negative (i.e., it lost mass) (-51±17 Gt yr^{-1} and -41±17 Gt yr^{-1}) in 1980-1990 and 1990-2000, respectively. Other ice discharge time series starting in 1985 (King et al., 2018, 2020, Mankoff et al., 2019, 2020) agree with (Mouginot et al., 2019, Figure 9.16). There is *limited evidence* of temporally and spatially heterogeneous Greenland outlet glacier evolution during 20th century (Lea et al., 2014; Lüthi et al., 2016; Andresen et al., 2017; Khan et al., 2020; Vermassen et al., 2020). Historical photographs (Khan et al., 2020) show large mass losses of Jakobshavn and Kangerlussuaq glaciers in West Greenland from 1880 until the 1940s, exceeding their 21st century mass loss, whereas the Helheim Glacier in East Greenland remained stable, gained mass in the 1990s then rapidly lost mass after 2000. Together, these 3 large outlet glaciers, draining ~12% of the ice sheet surface area, have lost 22±3 Gt yr^{-1} in the period 1880-2012 (Khan et al., 2020). Overall, these studies provide a variable picture of the Greenland Ice Sheet mass change in the 20th

ACCEPTED VERSION SUBJECT TO FINAL EDITING

century. The updated mass loss of Greenland Ice Sheet including peripheral glaciers for period 1901-1990 is 120 [70–170] Gt yr^{-1} (see Table 9.5 and Figures 9.16, 9.17).

Post-1992, the SROCC stated that it is *extremely likely* that the rate of mass change of Greenland Ice Sheet was more negative during 2012-2016 than during 1992-2001, with *very high confidence* that summer melting has increased since the 1990s to a level unprecedented over at least the last 350 years. Since the SROCC, the updated synthesis of satellite observations by the Ice Sheet Mass Balance Intercomparison Exercise (The IMBIE Team, 2020) and the GRACE Follow-On (GRACE-FO) Mission (Abich et al., 2019; Kornfeld et al., 2019), have confirmed the mass change record and the record has been extended to 2020 (The IMBIE team, 2021) as presented in 2.3.2.4.. The Greenland Ice Sheet lost 4890 [4140–5640] Gt of ice between 1992 and 2020, causing sea level to rise by 13.5 [11.4–15.6] mm (The IMBIE Team, 2021) (Section 2.3.2.4.1; Figure 9.16, Table 9.5). The IMBIE Team (2020) estimates are consistent with other post-AR5 reviews (Figure 9.17, Table 9.SM.1) (Bamber et al., 2018a; Cazenave et al., 2018; Mouginot et al., 2019; Slater et al., 2021). Recent GRACE-FO data (Sasgen et al., 2020; Velicogna et al., 2020) show that after two cold summers in 2017 and 2018, with relatively moderate mass change of about -100 Gt yr^{-1}, the 2019 mass change (-532 ± 58 Gt yr^{-1}) was the largest annual mass loss in the record. The *high agreement* across a variety of methods confirms the SROCC and Chapter 2 assessments. The mass-loss rate was on average 39 [–3 to 80] Gt yr^{-1} over the period 1992–1999, 175 [131 to 220] Gt yr^{-1} over the period 2000–2009 and 243 [197 to 290] Gt yr^{-1} over the period 2010–2019 (see Table 9.SM.1).

[START FIGURE 9.16 HERE]

Figure 9.16: Mass changes and mass change rates for Greenland and Antarctic ice sheet regions. (Upper Left) Time series of mass changes in Greenland for each of the major drainage basins shown in the inset figure (Bamber et al., 2018b; Mouginot et al., 2019) for the periods 1972 – 2018 and 1992-2018. (Upper Right) Time series of mass changes for three portions of Antarctica (Bamber et al., 2018b) for the period 1992 – 2018. (Lower rows) Estimates of mass change rates of surface mass balance, discharge and mass balance in seven Greenland regions (Bamber et al., 2018b; Mankoff et al., 2019; Mouginot et al., 2019; King et al., 2020). Estimates of mass change rates of surface mass balance, discharge and mass balance for three regions of Antarctica (Bamber et al., 2018b; The IMBIE Team et al., 2018; Rignot et al., 2019). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.16 HERE]

The SROCC assessed with *high confidence* that surface mass balance (SMB), rather than discharge, has started to dominate the mass loss of the Greenland Ice Sheet (due to increased surface melting and runoff), increasing from 42% of the total mass loss for 2000–2005 to 68% for 2009–2012. While these estimates have been confirmed since the SROCC (Mouginot et al., 2019), the new longer record, as well as further comprehensive studies (Khan et al., 2015; Colgan et al., 2019; Mottram et al., 2019; The IMBIE Team, 2020) and detailed discharge records (King et al., 2020; Mankoff et al., 2020) reveal a more complex picture than the continuous trajectory this statement may have implied. Discharge was relatively constant from 1972-1999, varying by around 6% for the whole ice sheet, while SMB varied by over a factor of two interannually, leading to either mass gain or loss in a given year (Figure 9.16). During 2000-2005, the rate of discharge increased by 18%, then remained fairly constant again (increasing by 6% from 2006-2018). After 2000, SMB decreased more rapidly than discharge increased. In summary, the consistent temporal pattern in these longer datasets leads to *high confidence* that the Greenland Ice Sheet mass losses are increasingly dominated by SMB, but there is *high confidence* that mass loss varies strongly, due to large interannual variability in SMB.

On a regional scale, the surface elevation is lowering in all regions, and widespread terminus and calving front retreats have been observed (with no glaciers advancing) (Mottram et al., 2019; Moon et al., 2020). The largest mass losses have occurred along the west coast and in southeast Greenland (Figure 9.16), concentrated at a few major outlet glaciers (Mouginot et al., 2019; Khan et al., 2020). This regional pattern is consistent with independent Global Navigation Satellite System (GNSS) observations from the Greenland

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GPS network which show elastic bedrock uplift of tens of centimetres between 2007-2019 as a result of ongoing ice mass loss (Bevis et al., 2019). The regional time series (Figures 9.16, Atlas.30) show that SMB has been gradually decreasing in all regions while the increase in discharge in the southeast, central east, northwest and central west has been linked to retreating tidewater glaciers (Figure 9.16). In summary, the detailed regional records show an increase in mass loss in all regions after the 1980s, caused by both increases in discharge and decreases in SMB (*high confidence*), although the timing and patterns vary between regions. The largest mass loss occurred in the northwest and the southeast of Greenland (*high confidence*).

[START FIGURE 9.17 HERE]

Figure 9.17: Greenland Ice Sheet cumulative mass change and equivalent sea level contribution. (a) A p-box (Section 9.6.3.2) based estimate of the range of values of paleo Greenland ice sheet mass and sea level equivalents relative to present day and the median over all central estimates (Simpson et al., 2009; Argus and Peltier, 2010; Fyke et al., 2011; Robinson et al., 2011; Colville et al., 2011; Dolan et al., 2011; Born and Nisancioglu, 2012; Miller et al., 2012b; Helsen et al., 2013; Nick et al., 2013; Quiquet et al., 2013; Stone et al., 2013; Dahl-Jensen et al., 2013; Lecavalier et al., 2014; Robinson and Goelzer, 2014; Colleoni et al., 2014; Koenig et al., 2015; Peltier et al., 2015; Calov et al., 2015; Stuhne and Peltier, 2015; Vizcaino et al., 2015; Calov et al., 2018; Dutton et al., 2015; Goelzer et al., 2016; Khan et al., 2016; Yau et al., 2016; de Boer et al., 2017; Simms et al., 2019); and (b) cumulative mass loss (and sea level equivalent) from 1972 (Mouginot et al., 2019) and 1992 (Bamber et al., 2018b; The IMBIE Team, 2019), the estimated mass loss from 1840 (Box and Colgan, 2013; Kjeldsen et al., 2015) indicated with a shaded box and projections from ISMIP6 by 2100 under RCP8.5/SSP5-8.5 and RCP2.6/SSP1-2.6 scenarios (thin lines from (Goelzer et al., 2020; Edwards et al., 2021; Payne et al., 2021) and *likely* and *very likely* range of the ISMIP6 emulation (shades and bold line (Edwards et al., 2021)) are shown as a timeseries. Schematic interpretations of individual reconstructions (Lecavalier et al., 2014; Goelzer et al., 2016; Berends et al., 2019) of the spatial extent of the Greenland ice sheet are shown for the (c) mid-Pliocene Warm Period, (d) the Last Interglacial and (e) the Last Glacial Maximum: grey shading shows extent of grounded ice. Maps of mean elevation changes (f) 2010-2017 derived from CryoSat 2 radar altimetry (Bamber et al., 2018b) and (g) ISMIP6 model mean (2093-2100) projected changes for the MIROC5 climate model under the RCP8.5 scenario (Goelzer et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.17 HERE]

The SROCC stated with *high confidence* that variability in large-scale atmospheric circulation is an important driver of short-term SMB changes for the Greenland Ice Sheet. This effect of atmospheric circulation variability on both precipitation and melt rates (and the SROCC assessment) is confirmed by more recent publications (Välisuo et al., 2018; Zhang et al., 2019a; Velicogna et al., 2020). The strong mass loss in 2019 (Cullather et al., 2020; Hanna et al., 2020; Tedesco and Fettweis, 2020) was driven by highly anomalous atmospheric circulation patterns, both on daily (Cullather et al., 2020) and seasonal timescales (Tedesco and Fettweis, 2020). Although surface melt is anticorrelated with the summer North Atlantic Oscillation index (Välisuo et al., 2018; Ruan et al., 2019; Sherman et al., 2020), especially in West Greenland (Bevis et al., 2019), Greenland Ice Sheet melt is more strongly correlated with the Greenland Blocking Index (Hanna et al., 2016, 2018) than with the summer North Atlantic Oscillation index (Huai et al., 2020).

The SROCC did not assess the role of cloud changes in detail. Studies since the AR5 have shown that higher incident shortwave radiation in conjunction with reduced cloud cover leads to increased melt rates, particularly over the low albedo ablation zone in the southern part of the Greenland Ice Sheet (Hofer et al., 2017; Niwano et al., 2019; Ruan et al., 2019). Conversely, an increase in cloud cover over the high-albedo central parts of the ice sheet, leading to higher downwelling longwave radiation, was shown to lead either to increased melt (Bennartz et al., 2013) or reduced refreezing of meltwater (van Tricht et al., 2016). The elevation dependence of the cloud radiative effect and its control on surface meltwater generation and refreezing (Wang et al., 2019c; Hahn et al., 2020) can induce a spatially consistent response of the integrated

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Greenland Ice Sheet melt to dominant patterns of cloudand atmospheric variability. The short- and longwave radiation effects on surface melt by clouds have been shown to compensate for each other during events of strong atmospheric rivers and the increase in melt is caused by increased sensible heat fluxes during such events (Mattingly et al., 2020). In summary, there is *medium confidence* that cloud cover changes are an important driver of the increasing melt rates in the southern and western part of the Greenland Ice Sheet.

The SROCC stated with *high confidence* that positive albedo feedbacks contributed substantially to the post-1990s Greenland Ice Sheet melt increase. Several, mostly positive, feedbacks involving surface albedo operate on ice sheets (e.g., Fyke et al., 2018). Melt amplification by the observed increase of bare ice exposure through snowline migration to higher parts of the ice sheet since 2000 (Shimada et al., 2016; Ryan et al., 2019) was five times stronger than the effect of hydrological and biological processes that lead to reduced bare ice albedo (Ryan et al., 2019). Impurities, in part biologically active (Ryan et al., 2018), have been observed to lead to albedo reduction (Stibal et al., 2017) and are estimated to have increased runoff from bare ice in the south-western sector of the Greenland Ice Sheet by about 10% (Cook et al., 2020). In summary, new studies confirm that there is *high confidence* that the Greenland Ice Sheet melt increase since about 2000 has been amplified by positive albedo feedbacks, with the expansion of bare-ice extent being the dominant factor, and albedo in the bare-ice zone being primarily controlled by distributed biologically active impurities (see also Section 7.3.4.3.

The SROCC reported with *medium confidence* that around half of the 1960-2014 Greenland Ice Sheet surface meltwater ran off, while most of the remainder infiltrated firn and snow, where it either refroze or accumulated in firn aquifers. Studies since SROCC show a decrease of firn air content between 1998-2008 and 2010-2017 (Vandecrux et al., 2019) in the low-accumulation percolation area of western Greenland, reducing meltwater retention capacity. Moreover, meltwater infiltration into firn can be strongly limited by low-permeability ice slabs created by refreezing of infiltrated meltwater (Machguth et al., 2016). Recent observations and modelling efforts indicate that rapidly expanding low-permeability layers have led to an increase in runoff area since 2001 (MacFerrin et al., 2019). In summary, there is *medium confidence* that meltwater storage and refreezing can temporarily buffer a large-scale melt increase but limiting factors have been identified.

The SROCC reported that there was *medium confidence* that ocean temperatures near the grounding zone of tidewater glaciers are critically important to their calving rate, but there was *low confidence* in understanding their response to ocean forcing. The increase in ice discharge in the late 1990s and early 2000s (Mouginot et al., 2019; King et al., 2020; Mankoff et al., 2020) has been associated with a period of widespread tidewater glacier retreat (Murray et al., 2015; Wood et al., 2021) and speed up (Moon et al., 2020). Since the SROCC, new studies provide strong evidence for rapid submarine melting at tidewater glaciers (Sutherland et al., 2019; Wagner et al., 2019; Bunce et al., 2020; Jackson et al., 2020b). Changes in submarine melting and subglacial meltwater discharge can trigger increased ice discharge by reducing the buttressing to ice flow and promoting calving (Benn et al., 2017; Todd et al., 2018; Ma and Bassis, 2019; Mercenier et al., 2020); through undercutting (Rignot et al., 2015; Slater et al., 2017b; Wood et al., 2018; Fried et al., 2019) and frontal incision (Cowton et al., 2019). Warming ocean waters have been implicated in the recent thinning and breakup of floating ice tongues in northeastern and northwestern Greenland (Mouginot et al., 2015; Wilson et al., 2017; Mayer et al., 2018; Washam et al., 2018; An et al., 2021; Wood et al., 2021). On decadal timescales, tidewater glacier terminus position correlates with submarine melting (Slater et al., 2019). Over shorter timescales, individual glaciers or clusters of glaciers can behave differently and asynchronously (Bunce et al., 2018; Vijay et al., 2019; An et al., 2021), and there are not always clear associations between water temperature and glacier calving rates (Motyka et al., 2017), retreat or speedup (Joughin et al., 2020; Solgaard et al., 2020). Variations in ice mélange at the front of a glacier, associated with changes in ocean and air temperature, have also emerged as a plausible control on calving (Burton et al., 2018; Xie et al., 2019; Joughin et al., 2020). In summary, there is *high confidence* that warmer ocean waters and increased subglacial discharge of surface melt at the margins of marine-terminating glaciers increase submarine melt, which leads to increased ice discharge, and *medium confidence* that this contributed to the increased rate of mass loss from Greenland particularly in the period 2000-2010 when increased discharge was observed in the southeast and northwest.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The SROCC reported that accurate bedrock topography is required for understanding and projecting the glacier response to ocean forcing. Accurate bathymetry is essential for both establishing which water masses enter glacial fjords and for reliable estimates of the submarine melt rates experienced by tidewater glaciers (Schaffer et al., 2020; Slater et al., 2020b; Wood et al., 2021). Subglacial and lateral topography is known to strongly modulate tidewater glacier dynamics and the sensitivity of tidewater glaciers to climatic forcing (Enderlin et al., 2013; Catania et al., 2018). Bathymetric mapping around the ice sheet has greatly improved with direct and gravimetric surveys (Millan et al., 2018; An et al., 2019a, 2019b; Jakobsson et al., 2020) leading to the improvement of Greenland-wide bathymetric and topographic mapping (e.g., Morlighem et al., 2017). However, large uncertainties in ice thickness remain for around half of the outlet glaciers (Mouginot et al., 2019; Wood et al., 2021) and sea-ice covered and iceberg-packed regions remain poorly sampled near glacier termini (Morlighem et al., 2017). There is *high confidence* that bathymetry (governing the water masses that flow into fjord cavities) and fjord geometry and bedrock topography (controlling ice dynamics) modulate the response of individual glaciers to climate forcing.

The AR5 assessed that it is *likely* that anthropogenic forcing contributed to the surface melting of Greenland since 1993 (Bindoff et al., 2013). Section 3.4.3.2 assesses that it is *very likely* that human influence has contributed to the observed surface melting of the Greenland Ice Sheet over the past two decades, and there is *medium confidence* of an anthropogenic contribution to recent mass loss from Greenland.

9.4.1.2 Model evaluation

The SROCC (Oppenheimer et al., 2019) stated that substantial challenges remained for modelling of both the Greenland surface mass balance and the dynamical ice sheet. Since the SROCC, further insights into modelling of the Greenland ice sheet has come from model intercomparison studies of both the surface mass balance (Fettweis et al., 2020) and dynamical ice sheets (Goelzer et al., 2020). Further aspects relevant to the forcing of the ice sheet from large scale global climate models and regional climate models are discussed in Box 9.3 and Section Atlas.11.2.

The SROCC stated that climate model simulations of Greenland surface mass balance (SMB) had improved since the AR5 giving *medium confidence* in the ability of climate models to simulate changes in Greenland SMB. Since the SROCC, a multi-model intercomparison study (Fettweis et al., 2020) of regional and global climate models has shown that the greatest inter-model spread occurs in the ablation zone, due to deficiencies in an accurate model representation of the ablation zone extent and processes related to surface melt and runoff, confirming the SROCC statement that bare-ice model uncertainty is large (Ryan et al., 2019). This intercomparison showed that simple, well-tuned SMB models using positive degree-day melt schemes can perform as well as more complex physically-based models (Figure Atlas.30). Furthermore, the ensemble-mean of the models produced the best estimate of the present-day SMB relative to observations (particularly in the ablation zone). Further assessment of Greenland ice sheet regional SMB can be found in Section Atlas 11.2.3. Recent progress confirms the SROCC assessment that there is *medium confidence* in the ability of climate models to simulate changes in Greenland SMB.

The SROCC noted increased use of coupled climate-ice sheet models for simulating the Greenland ice sheet, but also that remaining deficiencies in coupling between models of climate and ice sheets (e.g., low spatial resolution) limited the adequate representation of the feedbacks between them. Some Earth System Models now incorporate multi-layer snow models and full energy balance models (Punge et al., 2012; Cullather et al., 2014; van Kampenhout et al., 2017; Alexander et al., 2019a; van Kampenhout et al., 2020) or use elevation classes to compensate for their coarser resolution (Lipscomb et al., 2013; Sellevold et al., 2019; Muntjewerf et al., 2020a, 2020b; Gregory et al., 2020). Resulting SMB simulations compare better with Regional Climate Models and observations (Alexander et al., 2019b; van Kampenhout et al., 2020), but remaining shortcomings lead to problems reproducing a present-day ice sheet state close to observations. In summary, there is *medium confidence* in quantitative simulations of the present-day state of the Greenland ice sheet in ESMs.

The SROCC (Meredith et al., 2019) stated that there is *low confidence* in understanding coastal glacier

ACCEPTED VERSION SUBJECT TO FINAL EDITING

response to ocean forcing because submarine melt rates, calving rates, bed and fjord geometry and the roles of ice mélange and subglacial discharge are poorly understood. Ice-ocean interactions remain poorly understood and difficult to model, with parameterizations often used for calving of marine-terminating glaciers (Mercenier et al., 2018) and submarine and plume-driven melt (Beckmann et al., 2019). Due to the difficulties of modelling the large number of marine-terminating glaciers and limited availability of high-resolution bedrock data, the majority of recent modelling work on Greenland outlet glaciers is focused on individual or a limited number of glaciers (Krug et al., 2014; Bondzio et al., 2016; Morlighem et al., 2016a; Muresan et al., 2016; Bondzio et al., 2017; Choi et al., 2017; Beckmann et al., 2019), or a specific region (Morlighem et al., 2019). Since the SROCC, using a flowline model that includes calving and submarine melting, Beckmann et al. (2019) concluded that the AR5 upscaling of contributions from four of the largest glaciers (Nick et al., 2013) overestimated the total glacier contribution from the Greenland ice sheet, due to differences in response between large and small glaciers. The regional study of Morlighem et al. (2019) confirms that ice-ocean interactions have the potential to trigger extensive glacier retreat over decadal timescales as indicated by observations (Section 9.4.1.1). A focus in continental ice sheet models has been the improved treatment of marine-terminating glaciers via inclusion of calving processes and freely moving calving fronts (Aschwanden et al., 2019; Choi et al., 2021). An improved bedrock topographic dataset (Morlighem et al., 2017) allows for ice discharge to be better captured for outlet glaciers in continental ice sheet models and simulations indicate that bedrock topography controls the magnitude and rate of retreat (Aschwanden et al., 2019; Rückamp et al., 2020). Overall, although there is *high confidence* that the dynamic response of Greenland outlet glaciers is controlled by bedrock topography, there is *low confidence* in quantification of future mass loss from Greenland triggered by warming ocean conditions due to limitations in current understanding of ice-ocean interactions, its implementation in ice sheet models, and knowledge of bedrock topography.

The SROCC (Oppenheimer et al., 2019) noted the progress made in Greenland Ice Sheet models since the AR5. New since the SROCC is a focus on improved representation of the present-day state of the ice sheet (Goelzer et al., 2018, 2020) (Box 9.3). Improvements are closely linked to the growing number and quality of observations (Section 9.4.1.1), new techniques to generate internally consistent input data sets (Morlighem et al., 2014, 2016b), wider use of data assimilation techniques (Larour et al., 2014, 2016; Perego et al., 2014; Goldberg et al., 2015; Lee et al., 2015; Schlegel et al., 2015; Mosbeux et al., 2016), increased model resolution (Aschwanden et al., 2016) and tuning of key processes such as calving (Choi et al., 2021). A remaining challenge is *low confidence* in reproducing historical mass changes of the Greenland Ice Sheet (Box 9.3). However, there is *medium confidence* in ice sheet models reproducing the present state of the Greenland Ice Sheet leading to *medium confidence* in current ability to accurately project its future evolution.

9.4.1.3 Projections to 2100

The AR5 and the SROCC projected that changes in Greenland surface mass balance (SMB) will contribute to sea level in 2100 by 0.03 (0.01 to 0.07) m SLE under RCP2.6 and 0.07 (0.03 to 0.16) m SLE under RCP8.5. New since the SROCC are projections of SMB obtained by an Earth system model, two regional climate models, and reconstructions based on temperature from the CMIP5 and CMIP6 ensembles (Hofer et al., 2020; Noël et al., 2021). The range of sea level contribution from Greenland surface mass balance in Noël et al. (2021) are comparable to the AR5 assessment when either CMIP5 or CMIP6 models are used while Hofer et al., (2020) find a greater mass loss across all CMIP6 emission scenarios when compared to CMIP5 scenarios. Using SSP5-8.5 instead of RCP8.5 increases the mean projected sea level from 2005-2100 by up to 0.06 m in the regional climate model simulations of Hofer et al., (2020) who attribute the difference mainly to a greater Arctic amplification and associated cloud and sea ice feedbacks in the CMIP6 SSP5-8.5 simulations. In summary, these new projections with fixed ice sheet topography do not provide sufficient evidence to change the AR5 and SROCC assessment.

Reviewing modelling studies since the AR5 (Church et al., 2013a), the SROCC (Oppenheimer et al., 2019) assessed Greenland's contribution to future sea level to be relatively similar to the AR5 (Table 9.2). The baseline for projections has shifted from 1986-2005, in the SROCC, to 1995-2014 in this report. Adjusted to the new 1995-2014 baseline by subtracting 0.01 m, the SROCC projected a *likely* contribution of 0.07 (0.03

ACCEPTED VERSION SUBJECT TO FINAL EDITING

– 0.11) m SLE under RCP2.6 and 0.14 (0.08 – 0.27) m SLE under RCP8.5 by 2100. Since the SROCC, new projections for the 21st century have included dynamic ice sheets coupled to Earth system models (Muntjewerf et al., 2020a; Van Breedam et al., 2020) or regional atmospheric models (Le clec'h et al., 2019) (Table 9.2). The coupled ESM-ice sheet CESM2-CISM2 model projects a sea level rise of 0.109 m in 2100 relative to 2015 under SSP5-8.5 (Muntjewerf et al., 2020a) and a similar contribution under the idealized 1% yr^{-1} increase in CO_2 scenario (Muntjewerf et al., 2020b). The CESM2-CISM2 simulations include ice sheet-atmosphere interactions and ice sheet surface meltwater is routed to the ocean. The coupled regional atmospheric model and ice sheet model (MAR-GRISLI) projects a sea level rise of 0.079 m in 2100 relative to 2000 under RCP8.5 (Le clec'h et al., 2019). An Earth System model of lower complexity coupled to an ice sheet model gives a sea level contribution of 0.025 to 0.064 m under RCP2.6 and 0.056 to 0.12 m under RCP8.5 (the range is due to four simulations with different parameter sets for the atmosphere model) (Van Breedam et al., 2020). Van Breedam et al., (2020) identify a simulation with a preferred parameter set, that projects 0.034 m for RCP2.6and 0.073 m for RCP8.5 Although the ocean does not directly force the ice sheet models in these simulations, the new coupled models allow for interactions between ice sheet dynamics, surface mass balance and local climate. The coupled projections fall within the lower bounds of the AR5 and the SROCC, and as these studies do not prescribe ocean forcing directly, it is possible that the dynamic response is underestimated.

Since the SROCC, projections of the Greenland Ice Sheet are also now available from ISMIP6 (Nowicki et al., 2016, 2020a; Box 9.3; Annex II; Figure 9.17). The ISMIP6 multi-model projections are corrected with an assessment of the historical dynamical response to pre-2015 climate forcing (Box 9.3). For the period 2015-2100, the ISMIP6 uncorrected multi-model ensemble projects a sea level contributions ranging from 0.01 to 0.05 m under RCP2.6, 0.04 to 0.14 m under RCP8.5 (Goelzer et al., 2020), 0.02 to 0.06 m under SSP1-2.6 and 0.08 to 0.25 m under SSP5-8.5 (Payne et al., 2021)(Table 9.2). The higher mass loss in the SSPs is attributed to a larger decrease in SMB due to the high climate sensitivity of the models used (Payne et al., 2021). This finding is confirmed by (Choi et al., 2021), where CMIP6 SSP5-8.5 SMB leads to larger ice loss than CMIP5 RCP8.5 while ice discharge is similar. As the ISMIP6 framework considers a subset of the RCPs/SSPs and CMIP models, SSP-based projections have been inferred from multiple approaches. First, the ISMIP6 CMIP5-forced (Goelzer et al., 2020) and CMIP6-forced (Payne et al., 2021) combined ensemble projections were corrected with the historical trend (Box 9.3) using bootstrapping. Second, an emulator of the ISMIP6 projections (Edwards et al., 9998, Box 9.3) is forced by distributions of global surface air temperature for each SSP from a two-layer energy budget emulator (Supplementary Material 7.SM.2) and then corrected with the historical trend in the same way. These two approaches result in projections that are similar in their median values to the AR5 and SROCC projections (Table 9.2), but differ in their range. Similar results are obtained when the AR5 parametric fit is applied to the ISMIP6 models (Table 9.2, Supplementary Material 9.SM.4.4), which is used to estimate rates of change and post-2100 projections (Sections 9.4.1.4, 9.6.3.2).

The SROCC noted that the study by Aschwanden et al.,(2019) projects a significantly higher Greenland contribution to sea level than the assessed *likely* range in the AR5 and the SROCC. Under RCP8.5, Aschwanden et al., (2019) found that Greenland could contribute up to 0.33 m to sea level by 2100 relative to 2000 (the ensemble member that best reproduces 2000-2015 mean surface mass balance from a regional climate model projects Greenland mass losses of 0.08 m SLE under RCP2.6 and 0.18 m SLE under RCP8.5.) The SROCC noted that the potentially high sea level in this study could be due to the assumption of spatially uniform warming which can overestimate surface melt rates. However, it also reflects the *deep uncertainty* surrounding atmospheric forcing, surface processes, submarine melt, calving and ice dynamics. Goelzer et al., (2020) ascribe 40% of the ISMIP6 multi-model ensemble spread to ice sheet model uncertainty, 40% to climate model uncertainty and 20% to ocean forcing uncertainty. We note that this finding reflects the current challenges associated with the representation of ice-ocean interactions in models, and the uncertainty in basal conditions (Section 9.4.1.2). However, this finding is consistent with the work of Aschwanden et al., (2019) and thus, there is *medium confidence* that uncertainty in mass loss from the Greenland Ice Sheet is dominated by uncertainty in climate scenario and surface processes, whereas uncertainty in calving and frontal melt play a minor role.

The SROCC stated that surface processes, rather than ice discharged into the ocean, will dominate Greenland

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ice loss over the 21st century, regardless of the emissions scenario (*high confidence*). This is confirmed by the ISMIP6 projections (Goelzer et al., 2020; Payne et al., 2021). The projected mass loss of Greenland is predominantly due to increased surface meltwater and loss in refreezing capacity resulting in decreasing SMB (*high confidence*), concurrent with rising temperatures and darkening of the ice sheet surface (Fettweis et al., 2013; Vizcaino et al., 2015; Le clec'h et al., 2019; Muntjewerf et al., 2020b, 2020a; Sellevold and Vizcaíno, 2020). Mass changes due to SMB and outlet glacier dynamics are linked (Goelzer et al., 2013; Fürst et al., 2015; Rückamp et al., 2020) as mass loss by one process decreases mass loss by the other (for example, SMB removes ice before it can reach the marine glacier terminus). There is *medium confidence* that the mass loss through ice discharge will decrease in the future (Fürst et al., 2015; Aschwanden et al., 2019; Golledge et al., 2019a), because an increase in mass loss (via increased discharge or surface runoff) leads, in most areas, to a retreat of the glacier margin onto land above sea level, isolating the ice sheet from marine influence.

In summary, it is *virtually certain* that the Greenland Ice Sheet will continue to lose mass this century under all emissions scenarios and *high confidence* that total mass loss by 2100 will increase with cumulative emissions. The sea level assessment (Section 9.6.3.3) is based on the emulated ISMIP6 projections allowing a more consistent approach to a wider range of climate and ocean forcings. The Greenland ice sheet is *likely* to contribute 0.06 (0.01 to 0.10) m under SSP1-2.6 and 0.13 (0.09 to 0.18) m under SSP5-8.5 by 2100 relative to 1995-2014. These projections (as well as those of AR5 and SROCC) are lower than the study of (Aschwanden et al., 2019) (or the range of possible sea level changes resulting from structured expert judgement (Bamber et al., 2019); Section 9.6.3.2), contributing to the *deep uncertainty* in projected sea level (Box 9.4). There is however *high confidence* that the loss from Greenland will become increasingly dominated by SMB and surface melt, as the ocean-forced dynamic response of glaciers will diminish as marine margins retreat to higher grounds.

[START TABLE 9.2 HERE]

Table 9.2: Projected sea level contributions in meters from the Greenland ice sheet by 2100 relative to 1995-2014, unless otherwise stated, for selected RCP and SSP scenarios. Italics denote partial contributions. Historical dynamic response omitted from ISMIP6 simulations is estimated to be 0.19 ± 0.10 mm yr^{-1} (0.02 m ± 0.01 m in 2100 relative to 2015). The climate forcing is described in Appendix 7.SM.2.

9.4.1.4 Projections beyond 2100

The AR5 (Church et al., 2013a) assessed the contribution from Greenland to sea level projections in 2300 as 0.15 m SLE in low emissions scenarios (~RCP2.6) and 0.31-1.19 m in high scenarios (~RCP6.0/RCP8.5). The SROCC (Oppenheimer et al., 2019) did not update the AR5 estimates given *limited evidence* and *low agreement* from three new studies (Vizcaino et al., 2015; Calov et al., 2018; Aschwanden et al., 2019). Since the SROCC, a new study gives a sea level contribution of 0.11 to 0.20 m in low- and 0.61 to 1.29 m in high-emissions scenarios (Van Breedam et al., 2020). The low emissions projections by Van Breedam et al., (2020) encompass the AR5 assessed contribution, while the high emissions are higher than that from the AR5. The 'optimal' ensemble member of Aschwanden et al., (2019) (Section 9.4.1.3) indicates that Greenland could contribute 0.25 m under RCP2.6 and 1.74 m under RCP8.5. Structured expert judgement (Bamber et al., 2019) projects Greenland losses of 0.54 (0.28-1.28) m under 2ºC warming and 0.97 (0.4-2.23) m under 5ºC warming. These studies therefore agree that the AR5 and SROCC assessments are at the low end of the range of projections. In addition, observations suggest that Greenland Ice Sheet losses are tracking the upper range of AR5 projections (Slater et al., 2020b). Therefore, we update the *likely* range for the contribution of the Greenland Ice Sheet to GMSL by 2300 to 0.11-0.25 m under RCP2.6 and 0.31-1.74 m under RCP8.5. However, given the uncertainty in climatic drivers used to project ice sheet change over the 21st century (Goelzer et al., 2020; Hofer et al., 2020; Noël et al., 2021) and the large range in simulations since AR5 extending beyond 2100, we only have *low confidence* in the contribution to GMSL by 2300 and beyond.

The role of the elevation-mass feedback for future projections of Greenland can be assessed from paleo simulations. Ice sheet model simulations of the Laurentide (Gomez et al., 2015; Gregoire et al., 2016) and Eurasian (Alvarez-Solas et al., 2019) ice sheets invoke at least some contribution to last glacial termination mass loss from SMB reduction, as a consequence of an elevation–mass balance feedback (Levermann and Winkelmann, 2016). In a model spanning Meltwater Pulse 1A this mechanism increased mass loss by approximately 66% (Gregoire et al., 2016) but in Last Interglacial simulations the effect of this feedback is shown to depend on the surface scheme of the climate model employed (Plach et al., 2019). Given the agreement between theoretical analyses and paleo-ice sheet model experiments there is *high confidence* that the elevation-mass balance feedback is most relevant at multi-centennial and millennial timescales, consistent with future-focused studies (Gregory et al., 2020, Aschwanden et al. 2019, Le clec'h et al., 2019).

The SROCC adopted the AR5 assessment that complete loss of Greenland ice, contributing about 7 m to sea level, over a millennium or more would occur for a sustained GMST between 1ºC (*low confidence*) and 4ºC (*medium confidence*) above pre-industrial levels. New studies since the SROCC (Gregory et al., 2020; Van Breedam et al., 2020) confirm this assessment (see also Figure 9.30). Clark et al., (2016) estimate a complete loss to take about 8000 years at 5.5°C and about 3000 years at 8.6°C. Based on agreement between new and previous studies there is therefore *high confidence* that the rate at which Greenland ice sheet commitment is realized depends upon the amount of warming.

Accounting for more detailed feedbacks between the atmosphere and the ice sheet (Gregory et al., 2020) found a gradual relationship between sustained global mean warming and the corresponding near-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

equilibrium ice sheet volume, in contrast to a sharp threshold as found by (Robinson et al., 2012). Rather than a climatically-controlled tipping point for irreversible loss of the Greenland Ice Sheet, (Gregory et al., 2020) found a threshold of irreversibility linked to ice sheet size, similar to previous work (Ridley et al., 2010). The results of Gregory et al., (2020) show that if the ice sheet loses mass equivalent to about 3-3.5 m of sea-level rise, it would not regrow to its present state, and 2m of the sea-level rise would be irreversible. At which point in time the current ice sheet might reach this critical volume depends on oceanic and atmospheric conditions, ice dynamics, and climate-ice sheet feedbacks (Gregory et al., 2020; Van Breedam et al., 2020), so projections differ in the magnitude and rate of temperature change to cross the threshold for irreversible loss. Projections from a large ensemble indicate that the mass threshold may be reached as early as in 400 years, if warming reaches as high as >10°C above present under extended RCP8.5 (Aschwanden et al., 2019). In summary, there is *high confidence* in the existence of threshold behaviour of the Greenland Ice Sheet in a warmer climate, however there is *low agreement* on the nature of the thresholds and the associated tipping points.

[START BOX 9.3 HERE]

BOX 9.3: Insights into land ice evolution from model intercomparison projects

Projections of ice sheets and glaciers in the AR5 (Church et al., 2013a) and the SROCC (Oppenheimer et al., 2019) were assessed by collecting single model studies (with the exception of glaciers in SROCC (Hock et al., 2019b)). Community benchmark experiments (ISMIP-HOM; (Pattyn et al., 2008) or Marine Ice Sheet Model Intercomparison Projects (MISMIP, (Pattyn et al., 2012); MISMIP3d, (Pattyn and Durand, 2013); MISMIP+ (Asay-Davis et al., 2016; Cornford et al., 2020)) have substantially advanced ice sheet modelling since the AR5. Model Intercomparison Projects (MIPs) now inform projections of both ice sheets and glaciers: the Ice Sheet MIP for CMIP6 (ISMIP6) (Section 9.4.1.3; 9.4.2.5), the Linear Antarctic Response MIP (LARMIP-2; Section 9.4.2.5) and GlacierMIP (Section 9.5.1.3).

Regional forcing for land ice intercomparison projects

Simulations of ice sheets and glaciers are dependent on forcing provided by atmosphere and ocean models. Despite progress in representing processes, reducing biases and increasing resolution, regional and global models still have difficulties reproducing observed regional air temperature, surface mass balance and ocean changes (Section 9.4.1.2, 9.4.2.2, Atlas.11). Assessment of CMIP5 and CMIP6 climate models, as forcing for land ice models, has been undertaken (Walsh et al., 2018; Barthel et al., 2020a; Marzeion et al., 2020; Nowicki et al., 2020b) with the aim of selecting the best available historical forcings and sampling potential regional future climate changes. Despite improvement in simulation of atmospheric forcing, persistent biases remain in CMIP5/6, which reduces the fidelity of historical and future simulations of land ice.

ISMIP6 initial state intercomparison projects (initMIP)

The ISMIP6 initial state intercomparison projects (initMIP) for the Greenland (Goelzer et al., 2018) and Antarctic (Seroussi et al., 2019) ice sheets were designed to understand the uncertainty in sea level projections resulting from the choice of initialization procedures used for projections of sea level (Nowicki et al., 2016). Participating modelling groups (Annex II) were free to decide on the initialization method used to bring ice sheet models to a present-day state with the effect of these choices captured in a control simulation (starting from the present day state, with no further climate forcing applied), which measures intrinsic model drift. Compared to the earlier SeaRISE intercomparison project (Bindschadler et al., 2013; Nowicki et al., 2013), the modelled present day ice sheets are in closer agreement with observations and the model drift has been reduced (Goelzer et al., 2018; Seroussi et al., 2019). Nonetheless, historical simulations remain challenging for ice sheet models, due to limited ice sheet observations prior to the satellite era and biases in the historical atmospheric and oceanic forcings from climate models (Nowicki and Seroussi, 2018).ISMIP6 and LARMIP-2 therefore did not provide a protocol for the historical runs used to bring the ice sheets to present-day, nor criteria for sub-selecting models from the multi-model ensemble based on ability to reproduce historical changes (Levermann et al., 2020a; Nowicki et al., 2020a).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ISMIP6 projections for the Greenland and Antarctic ice sheets

The ISMIP6 projection protocol (Nowicki et al., 2016, 2020a) was designed to sample the uncertainty in future sea level due to climate scenarios (via the use of high and low emission scenarios and multiple climate models), ice-ocean interactions and inland response to ice shelf collapse, and ice sheet model diversity. The participanting ice sheet models are listed in Annex II. For each ice sheet, forcing was selected (Barthel et al., 2020b) from the CMIP5 (Taylor et al., 2012) and CMIP6 (Eyring et al., 2016) models. Atmospheric forcing fields consisted of anomalies in surface mass balance and surface air temperatures generated directly from the CMIP models for the Antarctic ice sheet and downscaled using the MAR regional climate model for the Greenland ice sheet (Hofer et al., 2020). To sample the uncertainty due to ocean forcings, models used either a model-specific scheme using the ISMIP6-provided oceanic dataset or a standard ISMIP6 approach. For the Greenland ice sheet, the oceanic dataset consists of thermal forcing (temperature minus freezing temperature) extrapolated into fjords and subglacial runoff. The standard approach uses timelines of tidewater glacier retreat (Slater et al., 2019, 2020a). For the Antarctic ice sheet, the oceanic dataset consists of salinity, thermal forcing and temperature added to an observationally derived climatology and extrapolated under ice shelves. The standard approach is a basal melt rate that depends quadratically on thermal forcing, adapted from Favier et al., (2019), with two different calibrations (Figure 9.19, Jourdain et al., 2020) that reproduce observed basal melt rates across Antarctica or Pine Island Glacier, respectively (Sections 9.4.2.2, 9.4.2.3). Antarctic ice shelf disintegration datasets (Nowicki et al., 2020a) assume that ice shelves disintegrate when annual surface melt reaches a threshold (Trusel et al., 2015).

The ISMIP6 projections (Goelzer et al., 2020; Seroussi et al., 2020; Payne et al., 2021) are reported as experiment minus control and represent the sea level resulting from future climate change only. The control simulation, which has constant climate conditions starting in 2015 from the historical run, captures drift associated with the choices made for the initialization method and historical run. Subtraction of this control removes any long-term dynamic response of the ice sheet to pre-2015 climate change. This response has been assessed using dynamic discharge derived from observations over the last 40 years (Mouginot et al., 2019; Rignot et al., 2019), under an assumption that it persists at the past rate until 2100 rather than diminishing. The dynamic response to historical forcing is estimated as 0.19 ± 0.10 mm yr^{-1} for the Greenland ice sheet (Section 9.4.1.3) and 0.33 ± 0.16 mm yr^{-1} for the Antarctic ice sheet (Section 9.4.2.5). Over the period 2015-2100, this leads to an additional sea level contribution of 1.7 cm for Greenland and 2.8 cm for Antarctica.

LARMIP-2 projections for the Antarctic ice sheet

LARMIP-2 is focused on the uncertainty in the ocean forcing and associated ice shelf melting (Levermann et al., 2014, 2020a) with the majority of the models also participating in ISMIP6 (Annex II). The experiments start from present day and impose an additional basal ice shelf melting of 8 m yr^{-1} at the beginning of the 100 yr simulation. A control run is used to remove drift resulting from initialization. The time derivative of the ice sheet response yields a linear response function, which is then convoluted with a forcing of basal shelf melt time series for five Antarctic regions. The forcing time series for RCP2.6, 4.5, 6.0 and 8.5 were obtained from a random combination of global mean temperature for each RCP from MAGICC-6.0 (Meinshausen et al., 2011), a scaling factor and time delay for the relationship between global surface air temperature and subsurface ocean warming in a given sector of the Southern Ocean from one of 19 CMIP5 models (Taylor et al., 2012) and a basal melting sensitivity from the interval [7,- 16] m yr^{-1} $^{o}C^{-1}$ to convert the regional subsurface warming into basal ice shelf melting. This process is repeated 20,000 times to obtain a probability distribution of the sea level contribution for five Antarctic sectors. The linear response framework captures complex temporal responses of the ice sheets resulting from an increase in basal ice shelf melting, but neglects the response to surface mass balance and any self-dampening or self-amplifying processes, such as MISI. The LARMIP-2 method is applied to temperature projections for the SSPs (Supplementary Material 7.SM.2) and an estimate of surface mass balance change from the AR5 parametric Antarctic ice sheet surface mass balance model (Church et al., 2013a) is added to the results (Sections 9.4.2.4, 9.4.2.5, 9.6.3.2). It is not necessary to add a long-term dynamic response to the LARMIP-2 projections, as this is incorporated in the basal melt time series.

GlacierMIP projections

GlacierMIP (Marzeion et al., 2020) was designed to estimate the glacier contribution to sea level rise,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

including from peripheral glaciers in Greenland and Antarctica that can be considered to be dynamically decoupled, or entirely separate, from the ice sheets. Glacier models are described in Annex II. Initial conditions were based on version 6 of the Randolph Glacier Inventory (RGI Consortium, 2017) and initial ice thickness and volume were provided from an update of Huss and Farinotti, (2012) (although some glacier models used their own estimates). Forcings were taken from ten different CMIP5 GCMs, selected based on availability of multiple RCPs, the choice in a previous model intercomparison (Hock et al., 2019a), and performance in glacier-covered regions according to Walsh et al., (2018). In addition, two global glacier models performed the same experiment with thirteen CMIP6 models (Section 9.5.1.3).

Use of an emulator with ISMIP6 and GlacierMIP projections

The ISMIP6 and GlacierMIP projections are primarily based on a limited number of CMIP5 RCPs and CMIP6 SSPs, and a limited sampling of ice-ocean interaction parameters and ice shelf collapse simulations. Emulators provide a method for expanding these projections to a range of SSPs with more comprehensive sampling of climate, ice sheet and glacier modelling uncertainties. Sections 9.4.1.3, 9.4.2.5 and 9.5.1.3 show estimates from the emulator of (Edwards et al., 2021). This is a Gaussian Process (rather than physically-based: Cross-Chapter Box 7.1) model derived from the ISMIP6 and GlacierMIP simulations; projections use distributions of GSAT from the two-layer emulator (Supplementary Material 7.SM.2) and ice sheet parameters as inputs, and include estimates of the emulator uncertainty. Probability intervals are therefore not inflated by a further factor, as is often the case for multi-model ensemble projections, to account for missing uncertainties (Section 9.6.3.2). The emulator is used in Section 9.6.3 to provide projections of the land-ice contribution to sea level that are fully consistent with each other, ocean heat content, and the assessed equilibrium climate sensitivity and projections of GSAT across the entire report.

[END BOX 9.3 HERE]

9.4.2 Antarctic Ice Sheet

9.4.2.1 Recent observed changes

As stated in Section 2.3.2.4, satellite observations by IMBIE combining multi-team estimates based on altimetry, gravity anomalies (GRACE) and the input-output method, already presented in the SROCC (Meredith et al., 2019), is updated and extended to 2020 (The IMBIE team, 2021). The Antarctic ice sheet (AIS) lost 2670 [1800–3540] Gt mass over the period 1992–2020, equivalent to 7.4 [5.0–9.8] mm global mean sea level rise (see Table 9.5 for contribution to sea-level budget and Figures 9.16, 9.18). Within uncertainties, this estimate agrees with a review of post-AR5 studies up to 2016 (Bamber et al., 2018b) and is consistent with recent single studies based on satellite laser altimetry (Smith et al., 2020), the input-output method (Rignot et al., 2019) and gravimetry (Velicogna et al., 2020). The mass-loss rate was on average 49 [-2 to 100] Gt yr^{-1} over the period 1992–1999, 70 [22 to 119] Gt yr^{-1} over the period 2000–2009 and 148 [94 to 202] Gt yr^{-1} over the period 2010–2016 (see Figures 9.16, 9.18 and Table 9.SM.1). However, recent work suggests that the mass loss has not further increased since 2016 because of regional mass gains in Dronning Maud Land (Velicogna et al., 2020). Mass loss of the West Antarctic and Antarctic Peninsula Ice Sheets has increased since about 2000 (*very high confidence*), essentially due to increased ice discharge (Harig and Simons, 2015; Paolo et al., 2015; Forsberg et al., 2017; Bamber et al., 2018b; Gardner et al., 2018; The IMBIE Team et al., 2018; Rignot et al., 2019)

The SROCC reported with *very high confidence* that the acceleration, retreat and thinning of the principal West Antarctic outlet glaciers has dominated the observed Antarctic mass loss over the last decades, and stated with *high confidence* that these losses were driven by melting of ice shelves by warm ocean waters. The average West Antarctic Ice Sheet (WAIS) mass loss of 82 ± 9 Gt yr^{-1} between 1992 and 2017 (The IMBIE Team et al., 2021) leads to substantial observed surface lowering (e.g., Schröder et al., 2019; Shepherd et al., 2019), particularly in coastal regions (Figure 9.18). Recent studies using satellite altimetry (Schröder et al., 2019) and the input-output method (Rignot et al., 2019) consistently show mass loss in these coastal regions since the late 1970s (Figure 9.16). Because of consistent multiple lines of evidence, there is *high confidence* in mass loss of the Totten Glacier in East Antarctica (Miles et al., 2013; Li et al., 2016b;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Mohajerani et al., 2018; Rignot et al., 2019; Schröder et al., 2019; Shepherd et al., 2019) since about 2000, dominated by changes in coastal ice dynamics (Li et al., 2016b). It is currently unclear whether mass loss of the East Antarctic Ice Sheet (EAIS) over the last three decades has been significant (Rignot et al., 2019) or, at 5 ± 46 Gt yr^{-1} between 1992 and 2017, essentially zero within uncertainties (The IMBIE Team et al., 2018). In summary, WAIS losses, through acceleration, retreat and thinning of the principal outlet glaciers, dominated the AIS mass losses over the last decades (*very high confidence*) and there is *high confidence* that this is the case since the late 1970s. Furthermore, parts of the EAIS have lost mass in the last two decades (*high confidence*).

As stated in the SROCC, snowfall and glacier flow are the largest components determining AIS mass changes, with glacier flow acceleration (dynamic thinning) on the WAIS and the Antarctic Peninsula driving total loss trends in recent decades (*very high confidence*), and a partial offset of the dominating dynamic-thinning losses by increased snowfall (*high confidence)*. The SROCC attributed *medium confidence* to estimates of 20th-century snowfall increases equivalent to a sea level change of -7.7 ± 4.0 mm on the EAIS and -2.8 ± 1.7 mm on the WAIS, respectively (Medley and Thomas, 2019). Loss of buttressing, which can be caused by ice shelf thinning, gradual ice shelf front retreat or ice shelf disintegration, has been linked to instantaneous ice velocity increases and thus dynamic thinning since the early 1990s. This link is clearly evident in the Amundsen and, to a lesser degree, Bellingshausen sectors (Gudmundsson et al., 2019), where passive shelf ice (ice that can be removed without major effects on the ice shelf dynamics) is very limited or absent (Fürst et al., 2016). Surface mass balance (SMB) changes, dominated by snowfall, exhibit strong regional and temporal variability, for example with multidecadal increases in the Antarctic Peninsula inferred since the 1930s (Medley and Thomas, 2019), and dominate the interannual to decadal variability of the AIS mass balance (Rignot et al., 2019). However, no significant continent-wide SMB trend is inferred since 1979 (The IMBIE Team et al., 2018; Medley and Thomas, 2019) (regional changes of Antarctic SMB are assessed further in Atlas Section 11.1). In summary, there is *very high confidence* that the observed AIS mass loss since the early 1990s is primarily linked to ice shelf changes.

[START FIGURE 9.18 HERE]

Figure 9.18: (a) A p-box (Section 9.6.3.2) based estimate of the range of values of paleo Antarctic ice sheet mass and sea level equivalents relative to present day and the median over all central estimates (Bamber et al., 2009; Argus and Peltier, 2010; Dolan et al., 2011; Mackintosh et al., 2011; Golledge et al., 2012; Miller et al., 2012b; Whitehouse et al., 2012; Golledge et al., 2013; Ivins et al., 2013; Argus et al., 2014; Briggs et al., 2014; Golledge et al., 2014; Maris et al., 2014; De Boer et al., 2015; Dutton et al., 2015; Golledge et al., 2015; Pollard et al., 2015; DeConto and Pollard, 2016; Gasson et al., 2016; Goelzer et al., 2016; Yan et al., 2016; de Boer et al., 2017; Golledge et al., 2017b; Kopp et al., 2017; Simms et al., 2019) ; and cumulative mass loss (and sea level equivalent) since 2015, with satellite observations shown from 1993 (Bamber et al., 2018a; The IMBIE Team et al., 2018; WCRP Global Sea Level Budget Group, 2018a) and observations from 1979 (Rignot et al., 2019), ISMIP6 projected changes by 2100 under RCP8.5/SSP5-8.5 and RCP2.6/SSP1-2.6 scenarios (thin lines from (Seroussi et al., 2020; Edwards et al., 2021; Payne et al., 2021) and 17th to 83rd, 5th to 95th percentile ranges of the ISMIP6 emulation (shaded line, (Edwards et al., 2021)). Right, 17th to 83rd, 5th to 95th percentile ranges for ISMIP6, emulator, and LARMIP-2 including SMB at 2100. Schematic interpretations of individual reconstructions (Anderson et al., 2002; Bentley et al., 2014; De Boer et al., 2015; Goelzer et al., 2016) of the spatial extent of the Antarctic ice sheet are shown for the (b) mid-Pliocene Warm Period, (c) the Last Interglacial and (d) the Last Glacial Maximum (Fretwell et al., 2013): grey shading shows extent of grounded ice. Maps of mean elevation changes (e) 1978-2017 derived from multi-mission satellite altimetry (Schröder et al., 2019) and (f) ISMIP6 (2061-2100) projected changes for an ensemble using the NorESM1-M climate model under the RCP8.5 scenario (Seroussi et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.18 HERE]

The SROCC stated with *high confidence* that melting of ice shelves by warm ocean waters, leading to reduction of ice shelf buttressing, has driven the observed ongoing thinning of major WAIS outlet glaciers.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Since the SROCC, digitized radar measurements have shown that the eastern ice shelf of Thwaites Glacier in the Amundsen Sea Embayment thinned between 10 and 33% during the three decades after 1978 (Schroeder et al., 2019), and the role of basal ice shelf melting has been emphasized (Smith et al., 2020). Strong surface meltwater production has been noted as a precursor of ice shelf disintegration in and since the SROCC (Bell et al., 2018), and recent work placed strong meltwater production events (Lenaerts et al., 2017; Nicolas et al., 2017; Wille et al., 2019) and seasons (Robel and Banwell, 2019) in this context. Antarctic ice shelf basal meltwater flux varied between about 1100±150 Gt yr^{-1} in the mid-1990s and about 1570±140 Gt yr^{-1} in the late 2000s before decreasing to 1160 ± 150 Gt yr^{-1} in 2018, and basal melt rates strongly vary with geographical position and depth, as a function of the surrounding water temperature (Adusumilli et al., 2020). Section 9.2.2.3 assesses that the intrusion of warm Circumpolar Deep Water, which has warmed and shoaled since the 1980s, has been at least partially controlled by forcing with significant decadal variability. *Limited evidence* suggests that beyond strong internal decadal wind variability, increased greenhouse gas forcing has slightly modified the mean local winds between 1920 and 2018, facilitating intrusion of Circumpolar Deep Water heat on the Amundsen-Bellingshausen continental shelf and increased ice-shelf melt (Section 9.2.2.3). However, theoretical understanding is still incomplete and in situ measurements within the ice-ocean boundary layer are sparse (Wåhlin et al., 2020). Moreover, modelling and therefore attribution of ice-shelf basal melt remains challenging because of insufficient process understanding, required spatial resolution, the paucity of in-situ observations (Dinniman et al., 2016; Asay-Davis et al., 2017; Turner et al., 2017), and uncertainties of bathymetric datasets under ice shelf cavities (Goldberg et al., 2019, 2020; Morlighem et al., 2020). In summary, ice shelf thinning, mainly driven by basal melt, is widespread around the Antarctic coast and particularly strong around the WAIS (*high confidence*), although basal melt rates show substantial spatio-temporal variability.

Satellite observations suggest that changes in sea ice coverage and thickness can modulate iceberg calving, ice-shelf flow and glacier terminus position around Antarctica (Miles et al., 2013, 2016, 2017; Massom et al., 2015; Greene et al., 2018; Bevan et al., 2019), either through mechanical coupling or via changes to ocean stratification, influencing basal melting. A combined observational and modelling study (Massom et al., 2018) showed that regional loss of a protective sea-ice buffer played a role in the rapid disintegration events of the Larsen A and B and Wilkins ice shelves in the Antarctic Peninsula between 1995 and 2009, by exposing damaged (rifted) outer ice-shelf margins to enhanced flexure by storm-generated ocean swells. One observational study (Sun et al., 2019) suggests that the absence of sea ice in front of ice shelves, which leads to strengthened topographic waves, favours ice shelf basal melt rates by increasing the baroclinic (depth varying) ocean heat flux which can enter the cavity (Wåhlin et al., 2020). Paleo evidence for sea ice control on ice sheets is lacking, but geologic evidence shows a concordance between periods of ice sheet growth and the expansion of sea ice (Patterson et al., 2014; Levy et al., 2019), both being favoured by reduced sea surface temperatures. Modelling confirms that sea ice controls the strength of ice mélange (Robel, 2017; Schlemm and Levermann, 2021) and thus influences ice shelf flexure and calving rates and stability of floating ice margins, but one model shows this had negligible effect on AIS retreat rates during past warm periods (Pollard et al., 2018). Loss of ice shelf-proximal sea ice is also associated with increased solar heating of surface waters and increased sub-shelf melting (Bendtsen et al., 2017; Stewart et al., 2019). In summary, although in some cases sea-ice decrease and glacier and ice shelf flow and terminus position changes can have the same common cause, there is *medium confidence* that sea ice decrease ultimately favours the mass loss of nearby ice shelves through a variety of processes.

The SROCC stated with *high confidence* that ice shelf disintegration has driven dynamic thinning in the northern Antarctic Peninsula over recent decades and expressed *high confidence* in currently ongoing mass loss from glaciers that fed now disintegrated ice shelves, although the mass loss rate has decreased in the 20 years since the immediate speed-up following ice shelf disintegration in 1995 and 2002. Observed flow speed of these tributary glaciers is still 26% higher than before the ice-shelf disintegration (Seehaus et al., 2018). Conversely, flow speed increase of the tributary glaciers of the Scar Inlet Ice Shelf has been interpreted as a sign of evolving instability of the currently intact ice shelf in one study (Qiao et al., 2020).

Ongoing grounding line retreat, indicating dynamic thinning, is observed with *high confidence* in many areas of Antarctica and particularly on the WAIS, with the highest rates being in the Amundsen and Bellingshausen Sea areas, and around Totten Glacier in East Antarctica, as stated in the SROCC. Research

ACCEPTED VERSION SUBJECT TO FINAL EDITING

published since the SROCC has evidenced grounding line retreat of the West Antarctic Berry Glacier on Getz Coast (Millan et al., 2020) and on the East Antarctic Denman Glacier (Brancato et al., 2020), both since 1996. Furthermore observed grounding line retreat in excess of 1.5 km between 2003 and 2015 has been reported for parts of Marie Byrd Land (Christie et al., 2018). In summary, there is *high confidence* that grounding lines of marine-terminating glaciers are currently retreating in many areas around Antarctica, and particularly around the WAIS, and additional areas of grounding line retreat have been evidenced since the SROCC.

The SROCC stated with *medium confidence* that sustained mass losses of several major glaciers in the Amundsen Sea Embayment (ASE) are compatible with the onset of Marine Ice Sheet Instability (MISI), but that whether unstable WAIS retreat had begun or was imminent remained a critical uncertainty. New publications since the SROCC have not substantially clarified this question. On the one hand, a study combining satellite measurements with a numerical model with prescribed ice shelf thinning (Gudmundsson et al., 2019) suggests that MISI is not required to explain the observed current mass loss rates of the WAIS, because they are consistent with external climate drivers. Furthermore, the fast grounding-line retreat of the Pine Island Glacier in the ASE, which was triggered in the 1940s (Smith et al., 2017), observed after 1992 (Rignot et al., 2014) and previously interpreted as a sign of MISI (Favier et al., 2014), seems to have stabilized recently (Milillo et al., 2017; Konrad et al., 2018), and its current flow patterns do not suggest ongoing or imminent MISI (Bamber and Dawson, 2020). On the other hand, sustained fast grounding line retreat has been observed for Smith Glacier in the ASE (Scheuchl et al., 2016), and an analysis of flow patterns and grounding line retreat of the ASE Thwaites Glacier between 1992 and 2017 (Milillo et al., 2019) showed sustained, albeit spatially heterogeneous, grounding line retreat, highlighting ice-ocean interactions that lead to increased basal melt. In addition, Denman Glacier in East Antarctica was shown to hold potential for unstable retreat (Brancato et al., 2020). In summary, the observed evolution of the ASE glaciers is compatible with, but not unequivocally indicating an ongoing MISI (*medium confidence*).

The SROCC reported *limited evidence* and *medium agreement* for anthropogenic forcing of the observed AIS mass balance changes. As stated in Section 3.4.3.2, there remains *low confidence* in attributing the causes of the observed mass of loss from the Antarctic ice sheet since 1993 in spite of some additional process-based evidence to support attribution to anthropogenic forcing.

9.4.2.2 Model evaluation

The AR5 (Church et al., 2013a; Flato et al., 2013) stated that regional climate models and global models with bias-corrected SST and sea ice concentration tended to produce more accurate simulations of Antarctic surface mass balance (SMB) than coupled climate models, and also noted strong climate model temperature biases over the Antarctic, though the latter may reflect known biases in the reanalysis used (Fréville et al., 2014). Section Atlas.11.1 assesses that there is *medium confidence* in the capacity of climate models to simulate Antarctic climatology and surface mass balance changes.

Section 9.2.3.2 assesses that there is *low confidence* in simulations of Southern Ocean temperature. Few ocean models resolve ice shelf cavities, and biases in present-day melt rates can be substantial in some sectors, including the key region of the Amundsen Sea (FESOM: Figure 9.19) (Naughten et al., 2018). An increasing number of observational studies from which basal melt rates are calculated (Huhn et al., 2018; Adusumilli et al., 2020; Das et al., 2020; Hirano et al., 2020; Stevens et al., 2020), combined with improved understanding of water-mass-specific influences and modes of melting or dissolving (Silvano et al., 2018; Adusumilli et al., 2020; Malyarenko et al., 2020; Wåhlin et al., 2020), may help to refine these models in the future. However, given the limited number of available models and their biases, there is currently *low confidence* in the sub-shelf melt rates simulated by ocean models.

Improvements in the representation of grounding line evolution in ice sheet models since the AR5 (such as sub-grid schemes for basal friction and ice shelf melt, and local grid refinement) means that most of the model simulations presented in the SROCC were dominated by physical processes. Since then, these advances have been applied in several model intercomparison projects (MISMIP+: Cornford et al., (2020);

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ABUMIP: Sun et al., (2020); ISMIP6 and LARMIP-2: Box 9.3). All models participating in ISMIP6 and LARMIP-2, for example, simulate ice shelf and grounding line evolution, and include subshelf melt parameterisation, which was not the case in the SeaRISE intercomparison (Bindschadler et al., 2013; Nowicki et al., 2013). Simulations of grounding line evolution (Seroussi et al., 2017, 2020) have benefited from improved bedrock topography (Morlighem et al., 2020). Treatment of subshelf melting, however, remains one of the causes of large differences in Antarctic ice sheet models, particularly for partially floating grid cells in models with coarse resolution (Levermann et al., 2020a; Edwards et al., 2021). Due to the limitations in resolving cavities in ocean models, as described above, basal melt rates are generally parameterized at the ice-shelf base, based on ocean model simulations of temperatures and salinity instead (Nowicki et al., 2020b; Seroussi et al., 2020). While this has the advantage of connecting melt rates to emission scenarios, a large variety of melt parameterisations exist (DeConto and Pollard, 2016; Lazeroms et al., 2018; Reese et al., 2018; Hoffman et al., 2019; Pelle et al., 2019; Jourdain et al., 2020), and there is *low agreement* due to limited observational constraints (ocean temperature, salinity, velocity, and ice shelf draft)(Jourdain et al., 2020), uncertainty in the physics of parameterized processes, missing processes (e.g., tides), and uncertainty in the treatment of ice-sheet–climate feedbacks (Donat-Magnin et al., 2017; Bronselaer et al., 2018; Golledge et al., 2019a). Parameterisations are usually calibrated to present-day melt rates, but can respond differently to projected ocean warming (Favier et al., 2019; Jourdain et al., 2020). Two different calibrations were used in ISMIP6 (Jourdain et al., 2020; Nowicki et al., 2020b;Box 9.3): one reproducing melt rates averaged around the whole continent (MeanAnt: Figure 9.19), and the other reproducing melt rates near the grounding line of Pine Island Glacier (PIGL: Figure 9.19), leading to large differences in melt rates. Evaluation with observations and two cavity-resolving models suggests that the MeanAnt parameterisation better reproduces observed melt rates and projected increases in both the warm Amundsen Sea Embayment and cold Ronne-Filchner shelf cavity, as well as total Antarctic melting (Jourdain et al., 2020). The PIGL calibration represents the upper end for increased basal melt sensitivity that would be caused by continent-wide changes to ocean water properties and circulation under strong future forcing (Jourdain et al., 2020). The basal sliding law also has a strong influence on grounding line retreat and glacier acceleration in response to perturbations, and varies spatially (Sun et al., 2020). Sliding laws (Joughin et al., 2019) can only be constrained with observations in regions experiencing significant change and with sufficiently long observational records.

[START FIGURE 9.19 HERE]

Figure 9.19: Ice shelf basal melt rates for present-day (upper panels) and changes from present-day to the end of the 21st century under the RCP8.5 scenario (lower panels). Present-day melt rates were estimated through: the input-output method constrained by satellite observations and atmosphere/snow simulations (Rignot et al., 2013) and representative of 2003-2008 (upper left); the non-local-PIGL parameterization constrained by observation-based ocean properties (Jourdain et al., 2020) and representative of 1995-2014 (upper centre); the Finite Element Sea-ice/ice-shelf Ocean Model (FESOM) simulation over 2006-2015, forced by atmospheric conditions from a CMIP5 multi-model mean (MMM) under the RCP8.5 scenario ((Naughten et al., 2018) upper right). Future anomalies are calculated as 2081-2100 minus present-day using the ISMIP6 non-local-MeanAnt and non-local-PIGL parameterizations (Jourdain et al., 2020) lower left and centre respectively) based on projections from the NorESM1-M CMIP5 model, and the FESOM-MMM projection (lower right). Note the symmetric-log colour bar (linear around zero, logarithmic for stronger negative and positive values). Inset highlights the Amundsen Sea Region. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.19 HERE]

The SROCC noted that Antarctic ice sheet simulations are increasingly evaluated or formally calibrated with modern observations and/or paleodata – to obtain more realistic initial conditions (ice sheet geometry, velocity and forcing) and to constrain uncertainty in probabilistic projections. This trend continues (Nias et

ACCEPTED VERSION SUBJECT TO FINAL EDITING

al., 2019; Gilford et al., 2020; Hamlington et al., 2020b; Wernecke et al., 2020). However, while the large-scale characteristics of the initial ice sheet state have improved significantly (Box 9.3), capturing the smaller-scale rates of change, including mass trends, remains challenging for many models (Goldberg et al., 2015; Reese et al., 2020; Seroussi et al., 2020; Siegert et al., 2020). This increases uncertainty in projections, especially for the 21st century (Section 9.4.2.5). Uncertainties in ice sheet model simulations have been, however, much better quantified since the AR5, through model intercomparison projects (in particular, ISMIP6 and LARMIP-2: Box 9.3), perturbed parameter ensembles, and increasing use of statistical emulation (Gilford et al., 2020; Levermann et al., 2020a; Wernecke et al., 2020; DeConto et al., 2021; Edwards et al., 2021) to better sample the parameter space. By exploring uncertainties more fully, these methods have the potential to identify better simulations of the historical period.

An important difficulty is how to evaluate simulations of processes that are not currently observed, or rare, or indirectly deduced: in particular, the ice shelf disintegrations and cliff failures that would drive the proposed Marine Ice Cliff Instability (MICI: Section 9.4.2.4 and Box 9.4)(DeConto and Pollard, 2016; DeConto et al., 2021). Models of ice cliff failure can only be indirectly and partially evaluated, using existing (i.e., static) cliffs and laboratory experiments (Clerc et al., 2019). The SROCC stated that there was *low agreement* on the exact MICI mechanism and *limited evidence* of its occurrence in the present or the past, and that the validity of MICI remains unproven. Only one ice sheet model represents MICI (Pollard et al., 2015; DeConto and Pollard, 2016; DeConto et al., 2021). The mechanism has not been found to be essential for reproducing Mid Pliocene Warm Period and Last Interglacial reconstructions or satellite observations, though Last Interglacial data slightly favours it in this model (Edwards et al., 2019a; Gilford et al., 2020; DeConto et al., 2021).

In summary, there is now *medium confidence* in many ice sheet processes in ice sheet models, including grounding line evolution. However, there remains *low confidence* in the ocean forcing affecting the basal melt rates and *low confidence* in simulating mechanisms that have the potential to cause widespread, sustained and very rapid ice loss from Antarctica through MICI.

9.4.2.3 Drivers of future Antarctic ice sheet change

Surface mass balance

The AR5 projected a negative contribution from Antarctic surface mass balance (SMB) changes to sea level over the 21st century (i.e., mitigating sea-level rise), due to increased snowfall associated with warmer air temperatures. Sensitivity of SMB to Antarctic surface air temperature change varied from 3.7 to 7 % $^{o}C^{-1}$, and the sea level projections assumed a sensitivity of 5.1 ± 1.5 % $^{o}C^{-1}$ from CMIP3 era models (Gregory and Huybrechts, 2006) to estimate SMB changes from Antarctic temperatures in the CMIP5 ensemble. Since the AR5, analyses of CMIP5 and CMIP6 models have found Antarctic temperature sensitivity for accumulation (precipitation minus sublimation) of 3.5 to 8.7 % $^{o}C^{-1}$ (Frieler et al., 2015), for SMB of 6.0 to 9.9 % $^{o}C^{-1}$ (Previdi and Polvani, 2016) and for precipitation of around 4 to 9% $^{o}C^{-1}$ (Bracegirdle et al., 2020) (± 1 s.d. ranges). An accumulation sensitivity estimate derived from ice core data lies in the middle of the range ~6% $^{o}C^{-1}$ (Frieler et al., 2015). These are consistent, within uncertainties, with each other and the AR5, under the approximation that SMB is dominated by snowfall.

The AR5 found that the median and *likely* sea level contributions due to SMB from 1986-2005 to 2100 were -0.05 (-0.09 to -0.02) under RCP8.5 and -0.02 (-0.05 to 0.00) m under RCP2.6. The SROCC did not present a separate SMB contribution, instead showing total Antarctic projections derived from ice sheet models (Section 9.4.2.5). Projections of the SMB contribution to sea level tend to be slightly more negative since the AR5, due at least in part to the higher range in equilibrium climate sensitivity values in CMIP6 (Payne et al., 2021). Mean and ± 1 s.d. ranges for grounded Antarctic ice sheet SMB changes from 2000 to 2100 computed from CMIP5 models are -0.08 (-0.13 to -0.04) m SLE for RCP8.5 and similarly for CMIP6 models are -0.07 (-0.11 to -0.03) m for SSP5-8.5 (Gorte et al., 2020). The GCMs used to drive ice sheet models in ISMIP6 (Box 9.3) project mean grounded AIS SMB changes from 2005 to 2100 of -0.06 (range -0.08 to -0.03) m SLE under RCP8.5 for the six CMIP5 models (Seroussi et al., 2020) and -0.09 (range -0.10 to -0.07) m SLE under SSP5-8.5 for the four CMIP6 models, which have climate sensitivity values of 4.8-5.3 ^{o}C (Payne et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2021). We apply the AR5 parametric AIS SMB model (Section 9.6.3.2) to updated projections of global mean temperature from a two-layer energy budget emulator (Supplementary Material 7.SM.2.), which gives a median -0.05 (5-95% range -0.07 to -0.02) m SLE for SSP5-8.5 (Section 9.4.2.5, Table 9.3), i.e., similar to the AR5 assessment and slightly smaller than the CMIP6 estimate. This estimate is used to augment the LARMIP-2 dynamic projections (Box 9.3) in Sections 9.4.2.5 and 9.4.2.6. Overall, then, CMIP5 and CMIP6 GCM simulations of sea level fall by 2100 due to Antarctic SMB increases are around 2-4 cm greater than estimates derived with the statistical method used in the AR5. Further details about projections of Antarctic temperature, precipitation and SMB are provided in Section Atlas.11.1.4, which assesses that, due to the challenges of model evaluation (Section 9.4.2.2) and the possibility of increased meltwater runoff (Kittel et al., 2021), there is only *medium confidence* that the future contribution of Antarctic SMB to sea level this century will be negative under all greenhouse gas emissions scenarios. Longer timescales are discussed in 9.4.2.6.

Sub-shelf melting

The SROCC highlighted that an important ongoing deficiency in projections of Antarctic sub-shelf melting is the lack of ice-ocean coupling in most continental-scale studies. Increased basal melting is mainly caused by warmer Circumpolar Deep Water (CDW; Section 9.2.2.3) on the continental shelves and warming surface waters intruding under ice shelves (Naughten et al., 2018). Predicting whether or not open ocean water masses will freely penetrate ice-shelf cavities, or will be partially blocked by ocean density gradients, is complex (Wåhlin et al., 2020), and whilst melting related to CDW inflow is currently dominant in the Amundsen Sea Embayment, melt in other embayments is limited by deep inflows of high salinity shelf water or seasonally-warmed shallow incursions of Antarctic Surface Water (Stewart et al., 2019; Adusumilli et al., 2020). There is little consensus regarding future change in CDW (Section 9.2.2.3), and more generally *low confidence* in future change in the temperature of Antarctic ice shelf cavities (Section 9.2.3.2).

The response of sub-shelf melting to ocean warming is also poorly constrained. A key unknown is whether, and when, cold ice shelf cavities might become more similar to the Amundsen Sea Embayment, not only in ocean temperature but also ice-ocean heat exchange, which depends on the cavity geometry and ocean circulation (Little et al., 2009). Only two ocean models with ice shelf cavities have been used to make subshelf basal melting projections for SRES and RCP scenarios (Hellmer et al., 2012; Timmermann and Hellmer, 2013; Timmermann and Goeller, 2017; Naughten et al., 2018). FESOM forced by a CMIP5 multi-model mean under RCP8.5 projects a 90% increase in melting (Figure 9.19), although this could be overestimated due to an underestimation of present day melt rates (Naughten et al., 2018)(Section 9.4.2.2). The temperature-melt relationship was parameterised by ISMIP6 in terms of heat exchange velocity in m a^{-1}, and by LARMIP-2 as basal melt sensitivity in m a^{-1} $^{o}C^{-1}$ (Box 9.3; (Jourdain et al., 2020; Levermann et al., 2020a; Reese et al., 2020), and both vary widely around the continent depending on cavity type. Median values of ISMIP6 heat exchange velocity vary by a factor of 5-10 when calibrating to either mean Antarctic or high Pine Island Glacier observed melt rates (Section 9.4.2.2; Box 9.3; (Jourdain et al., 2020). Basal melt sensitivities near the grounding line estimated by Reese et al., (2020) with a box model of ocean overturning range from 3.9 m a^{-1} $^{o}C^{-1}$ for the Weddell Sea to 10.5 m a^{-1} $^{o}C^{-1}$ for the Amundsen Sea region, with a continental mean of 5.3 m a^{-1} $^{o}C^{-1}$. Similarly high Amundsen Sea sensitivities are estimated in coupled ice-ocean simulations of Thwaites Glacier (mean 9.4 m a^{-1} $^{o}C^{-1}$; range 6 to 16 m a^{-1} $^{o}C^{-1}$)(Seroussi et al., 2017). These large variations lead to large differences in basal melt rates and projected sea level contributions when applied to the whole ice sheet in ISMIP6 and LARMIP-2 (Box 9.3). Projections of melt rates from the two ISMIP6 calibrations are higher than those from FESOM driven by a CMIP5 multi-model mean (Figure 9.19; Jourdain et al., 2020). The ISMIP6 ensemble mostly uses the mean Antarctic calibration, but includes some simulations with the Pine Island Glacier calibration and the ISMIP6 emulator samples more of these higher values; LARMIP-2 use basal melt sensitivities (7 to 16 m a^{-1} $^{o}C^{-1}$) consistent with estimates for the Amundsen Sea Embayment. Due to the limited availability of cavity-resolving ocean models and the wide regional variation in estimates of basal melt sensitivity to ocean temperature, there is therefore only *low confidence* in projected future sub-ice shelf melt rates. The impact of this uncertainty on Antarctic ice sheet model projections to 2100 is discussed in Section 9.4.2.5.

Ice shelf disintegration

Antarctic ice shelves modulate grounded ice flow through buttressing, so their weakening or disintegration is

ACCEPTED VERSION SUBJECT TO FINAL EDITING

crucial for the timing and magnitude of ice loss and onset of instabilities (Section 9.4.2.4; Box 9.4). Projections of ice shelf disintegration are uncertain in terms of both atmospheric warming and the response of the shelf surface (surface melting, and whether shelves then disintegrate due to hydrofracturing and flexing, or are resilient through refreezing or drainage; (Bell et al., 2018). The SROCC stated it is not expected that widespread ice shelf loss will occur before the end of the 21st century, but this was based on only one study, using a regional climate model forced by five GCMs (Trusel et al., 2015), so there was *low confidence* in this assessment. The study of DeConto and Pollard (2016) projected the appearance of extensive surface meltwater several decades earlier than (Trusel et al., 2015) and was therefore assessed to be too uncertain to include in the SROCC projections of the Antarctic ice sheet.

Since the SROCC, further studies have highlighted the modelling uncertainties in this area. Coastal surface air temperature projections in CMIP6 models show large inter-model differences driven by sea ice retreat, and exhibit more warming relative to global mean temperature under low emissions than high, due to delayed response of the Southern Ocean to stabilised emissions and stratospheric ozone recovery (Bracegirdle et al., 2020). The updated study of DeConto et al., (9998) includes improvements to the climate simulations relative to those in DeConto and Pollard, (2016) and the resulting surface meltwater projections are now consistent with Trusel et al., (2015). However, the net effect of meltwater feedbacks on ice shelves is uncertain. Ice discharge is expected to lead to surface ocean and atmosphere cooling: this increases ocean stratification and sub-shelf melting, but also reduces ice shelf surface melting and delays hydrofracturing (Golledge et al., 2019a; Sadai et al., 2020; DeConto et al., 2021). The new studies are insufficient to change the SROCC *low confidence* assessment on ice shelf loss. The consequence of this uncertainty on projections is discussed in Section 9.4.2.5 and Box 9.4.

9.4.2.4 Ice sheet instabilities

A major uncertainty in future Antarctic mass losses is the possibility of rapid and/or irreversible ice losses through instability of marine parts of the ice sheet, proposed via the mechanisms of Marine Ice Sheet Instability (MISI) and Marine Ice Cliff Instability (MICI), and whether these processes will lead to a collapse of the West Antarctic ice sheet (WAIS).

MISI is a proposed self-reinforcing mechanism within marine ice sheets that lie on a bed that slopes down towards the interior of the ice sheet, whereby, in the absence of ice shelf buttressing, the position of the grounding line is inherently unstable until reaching an upward sloping bed. The SROCC (Meredith et al., 2019) noted advances in modelling MISI since the AR5, but that 'significant discrepancies' remained in projections due to poor understanding of mechanisms and lack of observational data to constrain the models. Since the SROCC, modelling uncertainties have been more thoroughly explored, rather than constrained. (compatibility of current observations in the Amundsen Sea Embayment with MISI is assessed in Section 9.4.2.1). Internal climate variability might either slow (Hoffman et al., 2019) or amplify (Robel et al., 2019) MISI, and stable grounding line positions can be reached on downward sloping beds if ice shelves provide buttressing (Sergienko and Wingham, 2019; Cornford et al., 2020). Ice sheet model simulations that remove all Antarctic ice shelves (and prevent them from reforming) show 2-10 m SLE Antarctic mass loss after 500 years due to MISI, of which WAIS collapse contributes 2–5 m (Sun et al., 2020), with the majority of the mass loss in the first one to two centuries. Much of the multi-model variation is due to the sliding law (Section 9.4.2.2). However, it is not expected that widespread ice shelf loss will occur before the end of the 21st century (Section 9.4.2.3; Box 9.4). A recent update of bed topography that has unveiled large and overdeepened subglacial troughs in East Antarctica potentially vulnerable to MISI (Morlighem et al., 2020) has only been used by a few models (Seroussi et al., 2020; Sun et al., 2020), so current projections could underestimate vulnerability in these regions. The sea level rise contribution of the Antarctic ice sheet therefore crucially depends on the behaviour of individual ice shelves and outlet glacier systems and whether they enter MISI for a given level of warming (Pattyn and Morlighem, 2020, Box 9.4). As for Antarctic simulations generally (Sections 9.4.2.2, 9.4.2.3), there is *medium confidence* in simulating MISI but *low confidence* in projecting the subshelf melting and ice shelf disintegration that drive it.

The SROCC noted *limited evidence* from geological records and ice sheet modelling suggesting that parts of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the AIS experienced rapid (centennial) retreat *likely* due to MISI between 20,000 and 9,000 years ago, and also described more uncertain evidence for the LIG and MPWP. Recent support for past MISI is provided by model simulations of the WAIS during the LIG (Clark et al., 2020), the British Ice Sheet during the last termination (Gandy et al., 2018) and the Laurentide Ice Sheet during the Younger Dryas (Pico et al., 2019), which show progressive retreat despite declining temperatures, indicative of a true (ice dynamic) instability. Direct observational evidence of rapid paleo-ice sheet grounding-line retreat is rare, but on the Larsen continental shelf retreat rates of >10 km yr^{-1} during the deglaciation have been estimated (Dowdeswell et al., 2020). MISI has also been inferred from sedimentological evidence of ice loss from Wilkes Subglacial Basin, East Antarctica (Bertram et al., 2018; Wilson et al., 2018; Blackburn et al., 2020) but these reconstructions cannot unambiguously identify unstable from progressive retreat. Therefore there is *limited evidence* to identify the operation of instability mechanisms such as MISI in paleo-ice sheet retreat.

The SROCC assessed that ice-sheet interactions with the solid Earth are not expected to substantially slow sea-level rise from marine-based ice in Antarctica over the 21st century (*medium confidence*), but that these processes could become important on multi-century and longer time scales. More recent modelling of deglaciation of the Ross Embayment by (Lowry et al., 2020) is consistent with this assessment. However, new projections for Pine Island Glacier (Kachuck et al., 2020) support previous work (Barletta et al., 2018) suggesting lower mantle viscosity in this region leads to a negative feedback on decadal time scales. Grounding-line stabilisation by the solid Earth response may therefore occur over the 21st century in the Amundsen Sea Embayment, where most mass loss is occurring (Section 9.4.2.1), but more generally occurs over multi-centennial to millennial timescales (*medium confidence*).

The MICI hypothesis describes rapid, unmitigated calving triggered by ice shelf collapse (Pollard et al., 2015). The SROCC noted that the MICI mechanism led one model (DeConto and Pollard, 2016) to lose mass far more rapidly, but excluded the mechanism from its projections due to uncertainty in the timing of the ice shelf disintegration (Section 9.4.2.3). They stated that MICI could lead to sea level contributions beyond 2100 considerably higher than the *likely* range projected by other models, but given the *low agreement* on the exact MICI mechanism and *limited evidence* of its occurrence in the present or the past (Section 9.4.2.2), its potential to affect future sea level rise was very uncertain. Since the SROCC, new simulations show later ice shelf disintegration, in agreement with other models (DeConto et al., 9998; Section 9.4.2.3), and therefore lower projections at 2100 (Section 9.4.2.5). New theoretical evidence suggests that ice cliff collapse may only occur after very rapid ice shelf disintegration caused by unusually high meltwater production (Clerc et al., 2019; Robel and Banwell, 2019), and that the subsequent rate of retreat depends on the terminus geometry (Bassis and Ultee, 2019). As SROCC noted, only Crane Glacier on the Peninsula has shown retreat consistent with MICI, after the Larsen B ice shelf collapsed, and MICI-style behaviour at Jakobshavn and Helheim glaciers in Greenland might not be representative of wider Antarctic glaciers. Observations from Greenland show that steep cliffs commonly evolve into short floating extensions, rather than collapsing catastrophically (Joughin et al., 2020). As assessed in Section 9.4.2.2 and 9.4.2.3, there is therefore *low confidence* in simulating mechanisms that have the potential to cause widespread, sustained and very rapid ice loss from Antarctica this century through MICI, and *low confidence* in projecting the driver of ice shelf disintegration.

In summary, poorly understood processes of instabilities, characterized by *deep uncertainty*, have the potential to strongly increase Antarctic mass loss under high greenhouse gas emissions on century to multicentury timescales (Box 9.4). These instabilities are therefore considered separately in assessments of the future contribution to GMSL (Sections 9.4.2.5, 9.4.2.6, 9.6.3.2, 9.6.3.5).

9.4.2.5 Projections to 2100

The AR5 assessed the median and *likely* (66-100% probability) sea level contributions of the Antarctic ice sheet (AIS) in 2100 relative to 1986-2005 to be 0.06 (-0.04 to 0.16) m SLE under RCP2.6 and 0.04 (-0.08 to 0.14) m SLE under RCP8.5 (Table 9.3; no change when using the AR6 baseline). The AR5 stated that only the collapse of the marine-based sectors of the AIS, if initiated, could cause global mean sea level to rise substantially above the *likely* range during the 21st century, with *medium confidence* this would not exceed

ACCEPTED VERSION SUBJECT TO FINAL EDITING

several tenths of a metre during this period. The assessment of the dynamical contribution had no dependence on emissions scenario, due to the lack of literature, so the decrease in sea level contribution in the higher emissions scenario was solely due to increased SMB (Section 9.4.2.3). The SROCC (Oppenheimer et al., 2019) assessed the total contribution based on five new ice sheet modelling studies that incorporated marine ice sheet dynamics, combining their estimates and interpreting the 5-95th percentile range of the resulting distribution as the *likely* range (17-83% probability interval, i.e., not open-ended as in the AR5). The median and *likely* range contributions by 2100 were 0.04 (0.01–0.11) m under RCP2.6 and 0.12 (0.03-0.28) m under RCP8.5 (Table 9.3). The positive scenario-dependence in the SROCC - where increases in dynamic losses driven by ocean warming and ice shelf disintegration under higher emissions (Section 9.4.2.3) dominate over increases in surface mass balance - arose from a combination of physical processes and model limitations. Modelling improvements in these studies included improved representations of grounding line response to drivers, more extensive exploration of uncertainties, and inclusion of a positive feedback of meltwater on climate (Golledge et al., 2019b). However, two of the projections did not include surface mass balance changes that would offset dynamic losses (Levermann et al., 2014; Ritz et al., 2015), and the scenario dependence may have been further amplified by highly sensitive subshelf melt parameterisations and use of simplified surface mass balance schemes (Golledge et al., 2015, 2019b; Bulthuis et al., 2019; Oppenheimer et al., 2019).

Since the SROCC, new projections have arisen from multi-model intercomparison projects ISMIP6 and LARMIP-2 (Box 9.3), with one model including MICI (Section 9.4.2.4) (DeConto et al., 2021)(Table 9.3). Corrections are added to allow comparison: all ISMIP6-derived projections have an estimate of the historical dynamical response to pre-2015 climate forcing added, which increases contributions (Box 9.3; Figure 9.18); the LARMIP-2 dynamic projections are combined with an estimate of surface mass balance, which decreases contributions (Sections 9.4.2.3, 9.6.3.2); and the ISMIP6 emulated and LARMIP-2 projections were re-estimated using the global surface air temperature distributions from the two-layer energy budget emulator described in Supplementary Material 7.SM.2. The majority of the new projections indicate that the AIS will overall lose mass and contribute to sea level rise, under all emissions scenarios. Most thinning occurs in the Amundsen Sea sector in WAIS and Totten Glacier in EAIS (Figure 9.18). The most negative contribution is -0.02 m (5th percentile of ISMIP6 combined RCP8.5 and SSP5-8.5 projections after correction) and the largest contribution is 0.57 m SLE (95th percentile; (Levermann et al., 2020b)), or 0.63 m SLE with MICI (95th percentile; (DeConto et al., 2021)). ISMIP6 ensemble ranges are wider for the high scenarios (RCP8.5/SSP5-8.5) than the low (RCP2.6/SSP1-2.6), in part because more simulations were available. The ISMIP6 simulations that apply an ice shelf collapse scenario based on exceedance of a surface meltwater threshold (Trusel et al., 2015) driven by CMIP5 models show only a small increase in mass loss (~0-0.04 m), mostly from the Peninsula, due in part to the small number of ice shelves predicted to collapse this century (Seroussi et al., 2020). Simulations driven by the CMIP5 model HadGEM2-ES, which has unusually extreme warming in the Ross Sea (Barthel et al., 2020b), show a larger mass loss (up to ~0.05 m) in East Antarctica under ice shelf collapse (Edwards et al., 2021). The ISMIP6 projections do not include the efficient meltwater drainage or atmospheric feedbacks that could reduce mass loss further (Seroussi et al., 2020).

The relationship between emissions scenario and AIS response varies across the studies, with emulated ISMIP6 projections showing a slight negative scenario-dependence in the median (-0.01 m) from SSP1-2.6 to SSP5-8.5, and LARMIP-2-based projections showing a slight positive scenario-dependence in the median (0.02 m) (Table 9.3). A lack of clear scenario-dependence in the median masks large individual variations across climate and ice sheet models, whereby the net AIS contribution response to emissions scenario depends on the relative magnitudes of the atmosphere, ocean and ice sheet responses (Barthel et al., 2020b; Seroussi et al., 2020; Edwards et al., 2021). Climate and ice sheet models do not project that the AIS response will be the same under high or low greenhouse gas emissions in 2100, but rather there is no consensus on the sign of the change. In contrast, strong scenario dependence is seen from RCP4.5 to RCP8.5 in projections that allow MICI (Section 9.4.2.4;(DeConto et al., 2021), though less so than earlier projections (DeConto and Pollard, 2016) due to later ice shelf disintegrations. A negative or positive scenario-dependence of the AIS response this century cannot be deduced from recent observations, because there is still *low confidence* in attributing the causes of observed mass loss (Section 9.4.2.1), and neither regional mass increases by surface mass balance nor regional mass losses by ice flow have a linear relationship with global mean temperature (Sections 9.4.2.1, 9.4.2.2, 9.4.2.3). There is therefore *low agreement* on the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

relationship between emissions scenario and AIS response. However, in the longer-term, mass loss is expected to dominate (Section 9.4.2.6).

The LARMIP-2 median projections are higher than those of the ISMIP6 emulator (by 0.04-0.07 m), and the 95th percentiles are two to three times higher. Two possible reasons for the differences between the emulated ISMIP6 and LARMIP-2 projections are assessed: the set of ice sheet models (Annex II) and the parameter values determining subshelf melt sensitivity to ocean temperature (Section 9.4.2.3; Box 9.3). Using only the thirteen ice sheet models common to ISMIP6 and LARMIP-2 reduces the LARMIP-2 median projections by 0.02-0.03 m SLE and the 95th percentiles by 0.04-0.08m SLE (Table 9.3), approximately halving the difference in medians but having relatively small effect on the upper end. Subshelf melt sensitivity has a larger effect, due to the wide variation of estimates from different regions and methods. Using only the Pine Island Glacier subshelf melt distribution (Sections 9.4.2.2, 9.4.2.3) in the ISMIP6 emulator gives a median Antarctic projection of ~0.08 m in 2100 in all scenarios before historical correction, compared with ~0 m using only the mean Antarctic distribution; the published projections use a joint distribution (Edwards et al., 2021). Reese et al., (2020) find that using the basal melt sensitivities of LARMIP-2 yield an order of magnitude greater mass loss under RCP8.5 than with the ISMIP6 mean Antarctic values. Halving the basal melt sensitivity parameter range (i.e., in line with a continental mean estimate: Section 9.4.2.3) would lead to a halving of the LARMIP-2 dynamic contribution. This would reconcile the LARMIP-2 and ISMIP6 emulator median and 95th percentile projections using the common subset of models within ~0.02-0.05 m. There is therefore *limited evidence* that the ISMIP6 and LARMIP-2 projections could be reconciled by using common ice sheet models and basal melt sensitivity values.

It is not possible to distinguish which of ISMIP6 and LARMIP-2 is more realistic due to limitations in historical simulations (Box 9.3) and understanding of basal melting (Section 9.4.3), so the projections are combined using a 'p-box' approach (Section 9.6.3.2). The mean of the ISMIP6 emulated and LARMIP-2 medians gives the assessed median projections, and the outer edges of the 17-83% ranges give the outer edges of the assessed *likely* (17-83%) ranges, i.e., encompassing the structural and parametric uncertainties of both methods, giving *medium confidence* in their combined projections. The main difference between this assessment and the SROCC is to increase the medians of the lower scenarios by 0.05-0.07 m, so that all SSPs are similar to the SROCC assessment of RCP8.5, and to substantially increase the upper ends of the *likely* ranges: by 0.14-0.16 m for RCP2.6/SSP1-2.6 and RCP4.5/SSP2-4.5, and 0.06 m for RCP8.5/SSP5-8.5. The increase relative to the SROCC is partly due to the increase in LARMIP-2 projections relative to the original LARMIP study (Levermann et al., 2014), arising from the larger number of participating ice sheet models (Levermann et al., 2020b). The historical dynamic response to pre-2015 climate forcing applied to the ISMIP6 emulator could be overestimated, due to the assumption of a constant future rate (Box 9.3). This assessment encompasses the SROCC and all projections since, except the 83rd percentiles of projections that allow MICI under RCP8.5 (DeConto et al., 2021) and the structured expert judgement under 5°C shown in the SROCC (Bamber et al., 2019). Both are used in further p-box estimates to give the outer limits of *low confidence* assessments (Section 9.6.3.2).

In summary, it is *likely* that the Antarctic ice sheet will continue to lose mass throughout this century under all emissions scenarios, i.e., that dynamic losses driven by ocean warming and ice shelf disintegration will *likely* continue to outpace increasing snowfall (*medium confidence*). The upper end of projections is not well constrained, due to different assumptions about the future sensitivity of subshelf basal melting to ocean warming and the proposed Marine Ice Cliff Instability triggered by ice shelf disintegration (Sections 9.4.2.3 and 9.4.2.4; Box 9.4).

[START TABLE 9.3 HERE]

Table 9.3: Projected sea level contributions in meters from the Antarctic ice sheet in 2100 relative to 1995-2014, unless otherwise stated, for selected RCP and SSP scenarios. Italics denote partial contributions. The historical dynamic response omitted from ISMIP6 simulations is estimated to be 0.33 ± 0.16 mm yr^{-1} (0.03 m ± 0.01 m in 2100 relative to 2015; Box 9.3). The climate forcing is described in Supplementary Material 7.SM.2.

9.4.2.6 Projections beyond 2100

The SROCC assessed the median and *likely* range of Antarctic sea level equivalent contributions at 2300 as 0.16 (0.07 – 0.37) m under RCP2.6 and 1.46 (0.60 – 2.89) m under RCP8.5, based on three studies. It was noted that *deep uncertainty* remained beyond 2100: whilst solid Earth feedbacks could reduce ice loss over

ACCEPTED VERSION SUBJECT TO FINAL EDITING

multi-century timescales, Marine Ice Cliff Instability (MICI; Section 9.4.2.4) might give contributions higher than the *likely* ranges. The SROCC also presented structured expert judgement (SEJ) projections for comparison (Bamber et al., 2019), which give higher values. Since the SROCC, three studies have made projections to 2300. Rodehacke et al., (2020) assessed two methods for implementing precipitation changes (based on repeating 2071-2100 forcings beyond 2100), which both gave negative projections at 2300 because the dynamic response was very small (-0.11 to -0.01 m SLE for RCP2.6; -0.25 to -0.07 m for RCP8.5 forcing). In contrast, simulations forced by 2081-2100 ocean-only projections under RCP8.5/SSP5-8.5 beyond 2100, using two implementations of the ISMIP6 'non-local' basal melt parameterisations (Box 9.3; Section 9.4.2.2) and two sliding laws, are all positive (0.08 m to 0.96 m SLE by 2300), though these do not include the negative contribution from surface mass balance changes (Lipscomb et al., 2021). Finally, DeConto et al., (9998) update projections for the MICI hypothesis (Section 9.4.2.4) using the extensions of the RCPs to 2300, and obtain far higher contributions: median (17-83%) ranges of 1.09 (0.71 to 1.35) m SLE under RCP2.6 and 9.60 (6.87 to 13.54) m SLE under RCP8.5. These are larger than previous estimates (DeConto and Pollard, 2016), particularly at the upper end: 0.68 (0.29 to 1.13) m SLE for RCP2.6 and 8.40 (7.47 to 9.76) m for RCP8.5 (Edwards et al., 2019b), which can largely be explained by the higher maximum ice-cliff calving rate. LARMIP-2 dynamic projections (Box 9.3) are also estimated under the extended SSPs and corrected with surface mass balance (as in Section 9.4.2.5), giving median (17-83%) ranges of 0.40 (0.18–0.78) m SLE at 2300 under SSP1-2.6 and 1.57 (0.68–3.14) m under SSP5-8.5. The longer timescale may invalidate the linear response assumption of LARMIP-2, which neglects any self-dampening or self-amplifying processes. The ranges of projections for 2300 without MICI (Golledge et al., 2015; Bulthuis et al., 2019; Levermann et al., 2020a; Rodehacke et al., 2020; Lipscomb et al., 2021); 'assessed ice-sheet contributions' in Section 9.6.3.5) are -0.14 to 0.78 m SLE under RCP2.6/SSP1-2.6, and -0.27 to 3.14 m SLE under RCP8.5/SSP5-8.5. The lower bounds are the 5th percentile of (Bulthuis et al., 2019) and the lowest mean/median from (Rodehacke et al., 2020), respectively; the upper bounds are the 83% percentiles of the LARMIP-2 estimates. These ranges are wider than the SROCC *likely* ranges, and more consistent with the SEJ (Bamber et al., 2019). However, projections in which Antarctica contributes much more than the assessed ranges under sustained very high greenhouse gas emissions, i.e., around 7–14 m to GMSL by 2300 (DeConto et al., 2021), cannot be ruled out and are taken as a sensitivity case (Section 9.6.3.5; Table 9.11). In summary, there is *high confidence* that Antarctic mass loss will be greater beyond 2100 under high greenhouse gas emissions than low, but the large range of projections mean we have only *low confidence* in the likely AIS contribution to GMSL by 2300 for a given scenario. *Deep uncertainty* remains in the role of Antarctic ice sheet instabilities under very high emissions.

The West and East Antarctic ice sheets are considered to be tipping elements, i.e., susceptible to critical thresholds. The SR1.5 (Hoegh-Guldberg et al., 2018) assessed that a threshold for WAIS instability may be close to 1.5–2°C (*medium confidence*), as only RCP2.6 led to long-term projections of less than 1 m (Golledge et al., 2015; DeConto and Pollard, 2016). Based on the agreement of a further study (Bulthuis et al., 2019), the SROCC confirmed that low emissions would limit Antarctic ice loss over multi-century timescales (*high confidence*), but it was not possible to determine whether this was sufficient to prevent substantial ice loss (*medium confidence*). Since the SROCC, new studies have revisited this topic (Garbe et al., 2020; Rodehacke et al., 2020; Van Breedam et al., 2020; DeConto et al., 2021; Lipscomb et al., 2021), allowing a more complete assessment along with other studies (Feldmann and Levermann, 2015; Clark et al., 2016; Golledge et al., 2017a; Edwards et al., 2019b) and the extension to LARMIP-2 above. The majority project 0–1.3 m SLE on multi-century timescales under scenarios of 1–2°C warming. Projections can increase up to 2 m SLE under high basal melt sensitivity to ocean warming (Section 9.4.2.3)(Lipscomb et al., 2021) or MICI (Section 9.4.2.4). On multi-millennial timescales (≥ 2,000 years), many projections remain below 1.6 m SLE under 1–2°C warming, i.e. less than about half of the West Antarctic ice sheet in sea level equivalent (see also Section 9.6.3.5 and Figure 9.30). Other studies project majority or total loss of WAIS under 1–2°C warming, exceeding 2 m SLE, under the higher end of the warming range (≥ 1.5°C), or high ocean warming (≥ 0.5°C) and/or high basal melting around WAIS, or MICI. All but two of these multi-millennial studies use variants of the same ice sheet model, though different modelling choices mean they can be considered quasi-independent. Simulations of previous interglacial periods often show near or total WAIS disintegration, with mass loss exceeding 3 m SLE (e.g. Figure 9.18), although limitations of these studies or inferences that can be drawn under different forcings limit confidence in the robustness of these as quantitative analogues (Sections 9.4.2.4, 9.6.2). Overall, increased evidence and agreement on the timescales

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and drivers of mass loss confirm the SR1.5 assessment that a threshold for WAIS instability may be close to 1.5–2°C (*medium confidence*), and that the probability of passing a threshold is larger for 2°C warming than for 1.5°C (*medium confidence*), particularly under strong ocean warming. New projections agree with previous studies that only part of WAIS would be lost on multi-century timescales if warming remains less than 2°C (*medium confidence*). There is *limited agreement* about whether complete disintegration would eventually occur at this level of warming, but *medium confidence* this would take millennia.

Under ~2–3°C peak warming, complete or near-complete loss of the West Antarctic ice sheet is projected in most studies after multiple millennia (*low confidence*), with continent-wide mass losses of ~2–5 m SLE or more; this could occur on multi-century timescales under very high basal melting (Lipscomb et al., 2021) or widespread ice shelf loss and/or MICI (Sun et al., 2020; DeConto et al., 2021) (*low confidence*). Mass losses under ~2–3°C warming could be less than 2 m SLE, particularly for multi-century timescales, low basal melting, or less responsive sliding laws. If warming exceeds ~3°C above pre-industrial, part of the East Antarctic ice sheet (typically the Wilkes Subglacial Basin) is projected to be lost on multi-millennial timescales (*low confidence*), with total AIS mass loss equivalent to around 6–12 m or more sea level rise; mass loss could be much smaller if the dynamic response is small (Bulthuis et al., 2019; Rodehacke et al., 2020), or much faster under widespread ice shelf loss and/or MICI (Sun et al., 2020; DeConto et al., 2021). A new study by Garbe et al., (2020) suggests that 6°C sustained warming and associated mass loss of ~12 m SLE may be a critical threshold beyond which the ice sheet re-organises to a new state, leading to large losses from East Antarctica (including the Aurora Subglacial Basin) and leading to a further 10 m sea level contribution per degree of warming; other studies also show much higher mass loss per °C at higher levels of warming (Van Breedam et al., 2020; DeConto et al., 2021) (Section 9.6.3.5; Figure 9.30).

The SROCC (Meredith et al., 2019; Oppenheimer et al., 2019) assessed that Antarctic mass losses could be irreversible over decades to millennia (*low confidence*). Garbe et al., (2020) show that the Antarctic ice sheet is always volumetrically smaller when regrowing under a given warming level than when it retreats under the same forcing, and that even if retreat followed by regrowth results in a net zero change in volume, the spatial distribution of mass may be altered, especially in parts of West Antarctica vulnerable to MISI. Projections that start reducing CO_2 concentrations from 2030 onwards, reaching pre-industrial levels around 2300, show sea level contributions exceeding 1 m by 2500 when including MICI (DeConto et al., 2021). New research therefore confirms the SROCC assessment that mass loss from the AIS is irreversible on decadal to millennial timescales (*low confidence*) (FAQ 9.1), and suggests that reducing atmospheric CO_2 concentrations or temperatures to pre-industrial levels may not be sufficient to prevent or reverse substantial Antarctic mass losses (*low confidence*).

9.5 Glaciers, permafrost and seasonal snow cover

9.5.1 Glaciers

9.5.1.1 Observed and reconstructed glacier extent and mass changes

Global glacier contribution

The AR5 (Vaughan et al., 2013) assessed glacier changes from studies based on the regions defined in the Randolph Glacier Inventory (RGI; version 2.0): a satellite observation-based, global inventory of glacier outlines for the year 2000. Following the SROCC (Hock et al., 2019b; Meredith et al., 2019), we report studies based on RGI version 6.0 (RGI Consortium, 2017). Increased volume of satellite observations and the inclusion of detailed regional glacier inventories has resulted in an improved inventory (RGI Consortium, 2017). A new consensus estimate for the ice thickness distribution of all glaciers in RGI 6.0 was obtained from an ensemble of five numerical models (although only one out of five models covered all regions (Farinotti et al., 2019)) calibrated and validated with the worldwide Glacier Thickness Database (GlaThiDa 3.0; (GlaThiDa Consortium, 2019; Welty et al., 2020)) where possible. The updated inventory shows decreases in estimated glacier volume in the Arctic, High Mountain Asia and Southern Andes, partially compensated by increases in Antarctica. 15% of the total glacier volume is estimated to be below sea level and would not contribute to sea-level rise if melted (Farinotti et al., 2019). Supplementary Material Table

ACCEPTED VERSION SUBJECT TO FINAL EDITING

9.SM.2 shows the inventory glacier area and mass for each region in the year 2000.

The SROCC found a globally coherent trend of glacier decline in the last decades despite large annual variability and regional differences (*very high confidence)*. Section 2.3.2.3 assesses the global glacier mass changes for the whole 20th century (see Table 9.5 for contribution to the sea-level budget, note that the peripheral glaciers in Greenland and Antarctica are added to the ice sheets for the budget). The AR6 assessment is based on Marzeion et al., (2015), using glacier-length reconstructions (Leclercq et al., 2011) and a glacier model forced by gridded climate observations (Marzeion et al., 2012), and not considering the estimated mass loss of uncharted glaciers (100± 50 Gt yr^{-1}) (Parkes and Marzeion, 2018). The time series are assumed independent resulting in larger uncertainty than presented in the SROCC (see also Section 9.6.1). The rate of global glacier mass loss (excluding the periphery of ice sheets) for the period 1901-1990 is estimated to be *very likely* 210 ± 90 Gt yr^{-1}, representing 16 [28 to 7]% of the glacier mass in 1901, in agreement with the SROCC within uncertainty estimates.

Since the SROCC, new regional estimates for the Andes (Dussaillant et al., 2019), High Mountain Asia (Shean et al., 2020), Iceland (Aðalgeirsdóttir et al., 2020), the European Alps (Davaze et al., 2020; Sommer et al., 2020) and Svalbard (Schuler et al., 2020), two new global (Ciracì et al., 2020; Hugonnet et al., 2021) and an ad-hoc estimate for the latest glaciological observations (Zemp et al., 2020) have extended the glacier mass change time series up to 2018/2019 (Figure 9.21 and Supplementary Material Table 9.SM.3). A reconciled global estimate for the period 1962 to 2019 has been compiled by Slater et al., (2021). However, in contrast to Slater et al., (2021), after 2000 this assessment is based on the first globally complete and consistent estimate of 21st-century glacier mass change from differencing of digital elevation models (Hugonnet et al., 2021) covering 94.7% of glacier area with glacier mass change for each glacier in the inventory produced with unprecedented accuracy. The estimates from (Hugonnet et al., 2021) agree within uncertainties with new and previous estimates at global (Hock et al., 2019b; Wouters et al., 2019; Zemp et al., 2019; Ciracì et al., 2020; Slater et al., 2021) and regional scale (Dussaillant et al., 2019; Aðalgeirsdóttir et al., 2020; Schuler et al., 2020; Shean et al., 2020). Excluding peripheral glaciers of ice sheets (RGI regions 5 and 19), glacier mass loss rate was *very likely* 170 ± 80 Gt yr^{-1} for the period 1971 to 2019 (8 [14 - 4]% of 1971 glacier mass), 210 ± 50 Gt yr^{-1} over the period 1993 to 2019 (6 [8 - 4]% of 1993 glacier mass) and 240 ± 40 Gt yr^{-1} over the period 2006-2019 (3 [4 - 2]% of 2006 glacier mass) (Sections 2.3.2.3, 9.6.1; Table 9.5[4]; Cross-Chapter Box 9.1). Including the peripheral glaciers of the ice sheets, the global glacier mass loss rate in the period 2000-2019 is *very likely* 266 ± 16 Gt yr^{-1} (4 [6 -3]% of glacier mass in 2000) with an increase in the mass loss rate from 240 ± 9 Gt yr^{-1} in 2000-2009 to 290 ± 10 Gt yr^{-1} in 2010-2019 (*high confidence*). These estimates are in agreement with the SROCC estimate and extend the period to 2018/19. In summary, new evidence published since the SROCC shows that during the decade 2010 to 2019 glaciers lost more mass than in any other decade since the beginning of the observational record (*very high confidence*; Figure 9.20; Section 8.3.1.7.1).

[START FIGURE 9.20 HERE]

Figure 9.20: Global and regional glacier mass change rate between 1960 and 2019. The time series of annual and decadal mean mass change are based on glaciological and geodetic balances (Zemp et al. (2019) and Zemp et al. (2020)). Superimposed are the 2002-2019 average rates by (Ciracì et al., 2020) based on the Gravity Recovery and Climate Experiment (GRACE), 2006-2015 estimated rates as assessed in SROCC and the new decadal averages (2000-2009 and 2010-2019) by Hugonnet et al. (2021). (*) New regional estimates for the Andes (Dussaillant et al., 2019), High Mountain Asia (Shean et al., 2020), Iceland (Aðalgeirsdóttir et al., 2020), Central Europe (Sommer et al., 2020) and Svalbard (Schuler et al., 2020) are also shown. The uncertainty reported in each study is shown. See Figure 9.2 for the location of each region. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.20 HERE]

[4] The periods in Table 9.5 end in 2018 leading to a slight difference in the values

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Regional glacier changes

A major advance since the SROCC is the availability of high accuracy mass loss estimates for individual glaciers (Hugonnet et al., 2021). These results show that during the last 20 years, the highest regional mass loss rates (>720 kg m^{-2} yr^{-1}) were observed in the Southern Andes, New Zealand, Alaska, Central Europe, and Iceland. Meanwhile, the lowest regional mass loss rates (<250 kg m^{-2} yr^{-1}) were observed in High Mountain Asia, the Russian Arctic, and the periphery of Antarctica. Glacier mass loss in Alaska (25% of 2000-2019 total mass loss), the periphery of Greenland (13%), Arctic Canada North (11%), Arctic Canada South (10%), the periphery of Antarctica (8%), the Southern Andes (8%) and High Mountain Asia (8%), represent the majority (83%) of the total glacier mass loss during the last 20 years (2000-2019).

The glacier mass loss rate from geodetic mass balance assessments in the Southern Andes during 2006-2015 was smaller (720 ± 70 kg m^{-2} yr^{-1}) (Braun et al., 2019; Dussaillant et al., 2019; Hugonnet et al., 2021) than previously assessed in the SROCC (860 ± 160 kg m^{-2} yr^{-1}), though within uncertainties. In the Central and Desert regions of the Southern Andes, an increase in mass loss from 2000-2009 to 2010-2018, and a high loss rate in Patagonia for the whole period, are observed (Dussaillant et al., 2019). Records of glacier mass loss in Peru (Seehaus et al., 2019a) and Bolivia (Seehaus et al., 2019b) in the period 2000-2016 show an increase in mass loss towards the end of the observation period. In Western North America, outside of Alaska and western Yukon, there was a fourfold increase in mass loss for 2009-2018 (860 ± 320 kg m^{-2} yr^{-1}) compared to 2000-2009 (203 ± 214 kg m^{-2} yr^{-1}) (Menounos et al., 2019), and in the Canadian Arctic there was a doubling of mass loss in the last two decades compared with pre-1996 (Noël et al., 2018; Cook et al., 2019). The peripheral glaciers in NE Greenland experienced a 23% increase in mass loss in 1980-2014 compared to the period 1910-1978/87 (Carrivick et al., 2019). In Iceland, 16 ± 4 % of the ~1890 glacier mass has been lost; about half of that loss occurred in the period 1994-2019 (Aðalgeirsdóttir et al., 2020). Glacier records starting in 1960 in Norway show that half of the observed glaciers advanced in the 1990s but all have retreated since 2000 (Andreassen et al., 2020). In Svalbard, glaciers have been losing mass since the 1960s with a tendency towards more negative mass balance since 2000 (Deschamps-Berger et al., 2019; Van Pelt et al., 2019; Morris et al., 2020; Noël et al., 2020; Schuler et al., 2020). A similar increase in mass loss has been observed for Franz Josef Land in the Russian Arctic (Zheng et al., 2018). Rapid retreat and downwasting throughout the European Alps in the early 21st century is reported (Sommer et al., 2020) and long term records, although limited, indicate sustained glacier mass loss in High Mountain Asia since ~1850, with increased mass loss in recent decades (Shean et al., 2020). In summary, although interannual variability is high in many regions, glacier mass records throughout the world show with *very high confidence* that the loss rate has been increasing in the last two decades (see also Section 8.3.1.7.1 and 12.4 for regional glacier assessment).

Section 2.3.2.3 assesses that the rate and global character of glacier retreat in the latter part of 20th century and finds the first decades of the 21st century appear to be unusual in the context of the Holocene (*medium confidence*) and the global glacier recession in the beginning of the 21st century to be unprecedented in the last 2000 years (*medium confidence)*. These assessments are supported by regional evidence. New reconstructions of the Patagonian Ice Sheet suggest that 20th-century glacial recession occurred faster than at any time during the Holocene (Davies et al., 2020). The reconstructions of glacier variations show that the glaciers in some regions are now smaller than previously recorded: since the mid-16th century in the Mont Blanc and Grindelwald regions of the European Alps (Nussbaumer and Zumbühl, 2012), since the 9th century in Norway (Nesje et al., 2012), and for the past 1800 years in NW Iceland (Harning et al., 2016, 2018). In Arctic Canada and Svalbard, many glaciers are now smaller than they have been in at least 4000 years (Lowell et al., 2013; Miller et al., 2013, 2017, Schweinsberg et al., 2017, 2018) and more than 40,000 years in Baffin Island (Pendleton et al., 2019). Although the millennial glacier length variation records are incomplete and discontinuous, and glacier fluctuations depend on multiple factors (e.g. temperature, precipitation, topography, internal glacial dynamics), there is a coherent relationship between rising temperatures, negative mass balance and glacier retreat on centennial timescales across most of the world. Glaciological and geodetic observations show that the rates of early 21st-century mass loss are the highest since 1850 (Zemp et al., 2015). For all regions with long-term observations, glacier mass in the decade 2010 to 2019 was the smallest since at least the beginning of the 20th century (*medium confidence*).

In contrast to the global glacier mass decline (Figure 9.21, Supplementary Material 9.SM.2, Table 9.5), a few

ACCEPTED VERSION SUBJECT TO FINAL EDITING

glaciers have gained mass or advanced due to internal glacier dynamics or locally restricted climatic causes. The SROCC discusses the "Karakoram anomaly" (centred on the western Kunlun range (at about 80°E/35°N), but also covering part of the Pamir and Karakoram ranges), where glaciers have been close to balance since at least the 1970s and had a slightly positive mass balance since the 2000s. Since the SROCC, new evidence suggests that this anomaly is related to a combination of low-temperature sensitivity of debris-covered glaciers, a decrease of summer air temperatures (Cross-Chapter Box 10.3), and an increase in snowfall possibly caused by increases in evapotranspiration from irrigated agriculture (Bonekamp et al., 2019; de Kok et al., 2020; Farinotti et al., 2020; Shean et al., 2020). However, a recent geodetic mass balance estimate suggests substantially increased thinning rates of High Mountain Asian glaciers after about 2010 (Hugonnet et al.,2021). There is *limited evidence* to assess whether the "Karakoram Anomaly" will persist in coming decades, but due to the projected increase in air temperature throughout the region its long-term persistence is *unlikely* (*high confidence*) (Kraaijenbrink et al., 2017; de Kok et al., 2020; Farinotti et al., 2020; Cross-Chapter Box 10.3).

Drivers of glacier change

The AR5 (Masson-Delmotte et al., 2013) noted that early-to-mid-Holocene glacier minima could be attributed to high summer insolation (*high confidence*), unlike the current situation. Since the AR5, new and improved chronologies of glacier size variations from the end of the last glacial period and the Holocene (e.g., Solomina et al., 2015, 2016; Eaves et al., 2019; Hall et al., 2019; Marcott et al., 2019; Bohleber et al., 2020; Davies et al., 2020; Palacios et al., 2020) confirm the dominant role of orbital forcing for millennial-scale glacier fluctuations but emphasize the role of other forcings – solar and volcanic activity, ocean circulation, sea ice and internal climate variability – in explaining the regional variability of glacier fluctuations at shorter time scales. Shakun et al., (2015) demonstrated that during the last deglacial transition (18-11 ka), the mid-to-low-latitude glacier retreat was driven by an increase in atmospheric CO_2 and global temperature.

In the Northern Hemisphere, where summer insolation decreased during the Holocene (Section 2.2.1), glaciers generally waxed (Briner et al., 2016; Kaufman et al., 2016; Lecavalier et al., 2017; Zhang et al., 2017; Axford et al., 2019; Geirsdóttir et al., 2019; Larsen et al., 2019; Luckman et al., 2020). Conversely, in the Southern Hemisphere, where summer insolation increased during the Holocene, glaciers generally waned (Solomina et al., 2015; Kaplan et al., 2016; Reynhout et al., 2019). However, these general global trends were modulated by regional climate variations in temperature and precipitation (Murari et al., 2014; Kaplan et al., 2016; Batbaatar et al., 2018; Saha et al., 2018) and there are a number of examples of this. A precipitation increase led to a local early Holocene (7-8 ka) glacier maximum in arid Mongolia (Gichginii Range). Glacier advances at ~9 ka in Southwest Greenland have been suggested to be a consequence of the freshwater pulse from the Laurentide Ice Sheet, which led to cooling in the Baffin Bay area (Schweinsberg et al., 2018). Lake sediments indicate that the glaciers in the region were smaller than today or absent between 8.6 and 1.4 ka BP (Larocca et al., 2020). Glaciers on the Antarctic Peninsula and in Patagonia during the Holocene were strongly affected by the Southern Westerly Winds, sea ice extent, and ocean circulation (García et al., 2020). Recent studies indicate that explosive volcanism can drive glacier advances (Solomina et al., 2015, 2016; Schweinsberg et al., 2018; Brönnimann et al., 2019). In summary, on millennial time scales over the Holocene, there is *high confidence* orbital forcing drove hemispheric-scale glacier variations, but new studies provide a nuanced picture of responses to a variety of regional-scale forcings.

Section 3.4.3.1 assesses new attribution studies for glaciers and finds that human influence is *very likely* the main driver of the global, near-universal retreat of glaciers since the 1990s. The SROCC assessed that it is *very likely* that atmospheric warming is the primary driver for the global glacier recession. Since the SROCC, a study of glaciers in New Zealand used event attribution to confirm a connection between extreme glacier mass loss years and anthropogenic warming (Vargo et al., 2020).

The SROCC stated with *high confidence* that besides temperature, other factors, such as precipitation changes or internal glacier dynamics, have modified the temperature-induced glacier response in some regions. Deposition of a thin layer (<2 cm) of light-absorbing particles (e.g., black carbon, brown carbon, algae, mineral dust or volcanic ash) can exert an important control on glacier mass balance, by decreasing

ACCEPTED VERSION SUBJECT TO FINAL EDITING

surface albedo and thus increasing absorbed shortwave radiation and melt (see also section 7.3.4.3. The SROCC found *limited evidence* and *low agreement* that this process has had a significant effect on observed long-term glacier changes. Several studies have shown melt increases due to the deposition of light-absorbing particles (Schmale et al., 2017; Wittmann et al., 2017; Sigl et al., 2018; Di Mauro et al., 2019, 2020; Magalhães et al., 2019; Constantin et al., 2020). Conversely, increasingly thick debris cover (>2-5 cm) on retreating glaciers can slow down glacier melt (Pratap et al., 2015; Brun et al., 2016). Although debris covers only about 4-7% of the total glacier area globally (Scherler et al., 2018; Herreid and Pellicciotti, 2020), many glaciers are heavily debris-covered in their lower reaches, especially in High Mountain Asia, the Caucasus, the European Alps, Southern Andes and Alaska, resulting in different responses to warming than similar clean-ice glaciers. A shift in regional meteorological conditions driven by the location and strength of the upper level zonal wind has been found to have forced recent high mass loss rates in Western North America (Menounos et al., 2019). High geothermal heat flux areas underneath glaciers and high energy dissipation in the flow of water and ice causes additional mass loss of the glaciers in Iceland (Jóhannesson et al., 2020), accounting for 20% of the mass loss since 1994 (Aðalgeirsdóttir et al, 2020). Glacier lake volume, in front of retreating glaciers, has increased globally by around 48% between 1990 and 2018 (Shugar et al., 2020), which can increase both subaqueous melt and calving. In summary, there is *high confidence* that non-climatic drivers have and will continue to modulate the first-order temperature response of glaciers in some regions.

[START FIGURE 9.21 HERE]

Figure 9.21: Global and regional glacier mass evolution between 1901 and 2100 relative to glacier mass in 2015. Reconstructed glacier mass change through the 20th century (Marzeion et al., 2015) and observed during 1961-2016 (Zemp et al., 2019). Projected (2015-2100) glacier mass evolution is based on the median of three Representative Concentration Pathways (RCPs) emission scenarios (Marzeion et al., 2020). Uncertainties are in all cases the 90% confidence interval. For a better comparison between regions, the maximum relative mass change was set to 200%, although for three regions, the volume changes between 1901 and 2015 exceeded that value. For the Low Latitude, New Zealand, and High Mountain Asia glaciers, the changes were larger than 1000%, 350%, and 250%, respectively. See Figure 9.2 for the location of each region. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.21 HERE]

9.5.1.2 Model evaluation

Since the AR5, glacier mass projections have been coordinated by the Glacier Model Intercomparison Project (GlacierMIP) (Hock et al., 2019a; Marzeion et al., 2020). The SROCC (Hock et al., 2019b) relied on six global-scale glacier models based on previously published glacier model projections (Hock et al., 2019a), and found with *high confidence* that glaciers will lose substantial mass by the end of the century but assigned *medium confidence* to the magnitude and timing of the projected glacier mass loss, because of the simplicity of the models, the limited observations in some regions to calibrate them and the diverging initial glacier volumes.

Since the SROCC, (Marzeion et al., 2020) projected 21st century global-scale glacier mass changes based on seven global-scale and four regional-scale glacier models (Annex II). All models used the same initial and boundary conditions, forming a more coherent ensemble of projections compared to the SROCC. Nevertheless, challenges remain because of scarcity of glacier thickness, surface mass balance and frontal ablation data for model calibration, but also due to uncertainties in glacier outlines, surface elevations and ice velocities. The global surface mass balance models are of varying complexity, including mass balance sensitivity approaches (van de Wal and Wild, 2001), temperature-index methods (Anderson and Mackintosh, 2012; Marzeion et al., 2012; Radić et al., 2014; Huss and Hock, 2015; Kraaijenbrink et al., 2017; Maussion et al., 2019a; Zekollari et al., 2019; Rounce et al., 2020) and simplified energy balance calculations (Sakai and Fujita, 2017; Shannon et al., 2019). Compared to simpler, empirical parameterizations, full energy-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

balance models are not necessarily the most appropriate choice for simulating future glacier response to climate change, even at the local scale (Réveillet et al., 2017, 2018), because of parameter and forcing uncertainties. All models account for glacier retreat and advance but only two models (Anderson and Mackintosh, 2012; Huss and Hock, 2015) include frontal ablation.

Secondary processes such as debris-cover thickening (e.g., Herreid and Pellicciotti, 2020), albedo changes due to light-absorbing particles (e.g., Magalhães et al., 2019; Williamson et al., 2019), trends of refreezing and water storage in firn (e.g., Ochwat et al., 2021), dynamic instabilities such as surges (e.g., Thøgersen et al., 2019) or glacier collapse (e.g., Kääb et al., 2018), are not represented in global glacier models, resulting in both underestimated and overestimated sensitivity to warming that is currently not possible to quantify. Furthermore, challenges for future projections are caused by the low resolution and high spatial variability at subgrid scale of the precipitation amount provided by GCMs, which requires downscaling to the spatial scale of a glacier (Maussion et al., 2019a; Zekollari et al., 2019; Marzeion et al., 2020). In summary, in agreement with the SROCC, progress in global scale glacier modelling efforts allows *medium confidence* in the capabilityof current-generation glacier models to simulate the magnitude and timing of glacier mass changes as a response to the climatic forcing.

9.5.1.3 Projections

The AR5 (Vaughan et al., 2013) and the SROCC (Hock et al., 2019b) stated with *high confidence* that the world's glaciers are presently in imbalance due to the warming of recent decades. The observed retreat of glaciers is only a partial response to the already realized warming (Christian et al., 2018), and they are committed to losing considerable mass in the future, even without further change in air temperature (Mernild et al., 2013; Trüssel et al., 2013; Zekollari and Huybrechts, 2015; Huss and Fischer, 2016; Marzeion et al., 2018; Jouvet and Huss, 2019). One model estimates that 36 ± 8 % of global glacier mass is already committed to be lost due to past greenhouse gas emissions (Marzeion et al., 2018). Although accumulation and ablation instantly determine the surface mass balance, the glacier geometries adjust to changed atmospheric conditions over a longer time (Zekollari et al., 2020). The adjustment time, often referred to as the response time, is variable from one glacier to another, depending on the glacier geometry (thickness and steepness), surface mass balance and gradient (e.g., Jóhannesson et al., 1989; Harrison et al., 2001; Lüthi, 2009; Zekollari et al., 2020). Response time is variable: years for smaller and steeper glaciers (Beedle et al., 2009; Lüthi and Bauder, 2010; Rabatel et al., 2013), up to tens or hundreds of years for larger and gentle-sloped glaciers (e.g., Burgess and Sharp, 2004; Lüthi et al., 2010; Zekollari et al., 2020). The models indicate that the disequilibrium between the glaciers and present atmospheric conditions (1995 to 2014) reduces and then disappears at around year 2070 (Marzeion et al., 2020). There is therefore *very high confidence* that the disequilibrium of glaciers will persist as warming continues and that glaciers will continue to lose mass for at least several decades because of their lagged response even if global temperature is stabilized.

The SROCC assessed that global glacier mass loss by 2100, relative to 2015 will be 18% [*likely* range 11 to 25%] for scenario RCP2.6 and 36% [*likely* range 26 to 47%] for RCP8.5, and that many glaciers will disappear regardless of the emission scenario (*very high confidence*). Since the SROCC, new results from (Marzeion et al., 2020) have been published (Box 9.3; Figure 9.21, Table 9.4, including peripheral glaciers in Greenland and Antarctica). Glaciers will lose 29,000 [9,000 to 49,000] Gt and 58,000 [28,000 to 88,000] Gt over the period 2015-2100 for RCP2.6 and RCP8.5, respectively (*medium confidence*), which represents 18 [5 to 31] % and 36 [16 to 56] % of their early 21st century mass, respectively (Table 9.4). Within uncertainties, these agree with the SROCC estimates, although with a slightly smaller mass loss due to the inclusion of models with lower sensitivity to changing climate conditions (Marzeion et al., 2020). The greatest source of uncertainty in glacier mass loss until the middle of the 21st century is the disagreement between glacier models, with emissions scenario becoming the dominant cause of uncertainty by the end of the 21st century (Marzeion et al., 2020).

Although the GlacierMIP projections (Hock et al., 2019a; Marzeion et al., 2020) were forced by RCP scenarios, two global glacier models (Huss and Hock, 2015; Maussion et al., 2019b) were also run with 13

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GCMs and SSP scenarios (Table 9.4). These results show increased mass loss compared to the RCP forced simulations, although with fewer global glacier models. To enable the glacier contribution to future sea level rise to be estimated under the full range of SSP scenarios (Section 9.6.3.3), the GlacierMIP results are emulated using a Gaussian Process model (Edwards et al., 2021) (Box 9.3, Table 9.4). The emulated projections show a narrower range than the roughly equivalent RCP projections, which may be explained by not accounting for covariance in the regional uncertainties (Marzeion et al., 2020) and by the fact that the emulator caps sea level contribution for each region at the volume above floatation estimated by (Farinotti et al., 2019) (Table 9.SM.2). Comparison of simulated and emulated regional sea level contributions support this explanation. Rates of change and post-2100 projections for the sea level projections are estimated with the AR5 parametric fit (Supplementary Material 9.SM.4.5;(Church et al., 2013a)) applied to the GlacierMIP results (Marzeion et al., 2020), and these are also shown in Table 9.4 for comparison.

[START TABLE 9.4]

[1] OGGM (Maussion et al., 2019a) and GloGEM (Huss and Hock, 2015)

[END TABLE 9.4]

The mass loss rates vary between regions and there are distinctively different patterns between scenarios (Marzeion et al., 2020). The global models agree that regions characterized by relatively little glacier-covered area (Low Latitude, Central Europe, Caucasus, Western Canada and US, North Asia, Scandinavia and New Zealand) will lose nearly all (>80%) glacier mass by 2100 in the RCP 8.5 scenario, but their corresponding contribution to sea-level rise will be small. A study using detailed ice dynamics for the largest glacier of the European Alps, Great Aletsch Glacier, projects 60% of present ice volume will be lost by 2100 in RCP2.6 and an almost complete wastage of the ice in RCP8.5 (Jouvet and Huss, 2019). Due to their larger mass, the largest contribution to sea level rise comes from glaciers in the Arctic and Antarctic regions (Antarctic, Arctic Canada, Alaska, Greenland, Svalbard and Russian Arctic), in spite of having the smallest relative mass loss, and it is expected that they will continue to contribute to sea level rise beyond 2100. The regions with intermediate glacier mass (Southern Andes, High Mountain Asia and Iceland) show decreasing mass loss rates for RCP2.6 throughout the 21st century, and increasing rates for RCP8.5 that peak in the mid to late 21st century (Figure 9.21). The peak in mass loss rate followed by reduction is due to both decreasing glacier volume and stabilizing mass balance (Marzeion et al., 2020). Vatnajökull, the largest glacierin Iceland, is projected to lose about 50% of its mass by 2300 in extended RCP4.5 and 80-100% in extended RCP8.5 scenarios (Schmidt et al., 2019). In summary, both global and regional studies agree that glacier mass loss will continue in all regions, with larger mass loss for high emission scenarios (*high confidence*) (see also Section 8.4.1.7.1).

In the AR5 and the SROCC, glacier mass loss beyond 2100 was calculated employing a parametric fit to available model simulations. In section 9.6.3.5, that same parametric fit is applied to (Marzeion et al., 2020) projections resulting in complete glacier mass loss at year 2300 under SSP5-8.5 and 40-100% mass loss under SSP1-2.6. (Clark et al., 2016) simulate glacier mass evolution, not including glaciers peripheral to the Antarctic ice sheet, for different warming levels for the next ten thousand years. There is *limited evidence* and *low confidence* that at sustained warming levels between 1.5 and 2°C, about 50-60% of glacier mass will remain, predominantly in the polar regions. At sustained warming levels between 2 and 3°C, about 50-60% of glacier mass outside Antarctica will be lost and at sustained warming levels between 3 and 5 °C, 60-75% of glacier mass outside Antarctica will disappear. Based on (Marzeion et al., 2020), there is *medium confidence* that nearly all glacier mass in low latitudes, Central Europe, the Caucasus, Western Canada and the US, North Asia, Scandinavia and New Zealand will disappear at this high warming level.

9.5.2 Permafrost

This section focuses on the physical aspects of permafrost (perennially frozen ground) as an element of the climate system, drawing on the assessment of observed global permafrost changes provided in Section 2.3.2.5, and treating more specifically model evaluation and projections. The permafrost carbon feedback is assessed in Box 5.1. Section 12.4 of this report provides permafrost information relevant to impacts and risk on regional scales.

9.5.2.1 Observed and reconstructed changes

The current extent of the global permafrost region is about $22 \pm 3 \times 10^6$ km^2 (Gruber, 2012). Permafrost underlies about 15% of Northern Hemisphere land and more than 50% of the unglacierized land north of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

60°N (Zhang et al., 1999; Gruber, 2012; Obu et al., 2019). It is also found in high-altitude areas of mountain ranges in both hemispheres (estimated in the SROCC (Hock et al., 2019b) as representing about 27-29% of the global permafrost area (*medium confidence*) and most unglacierized areas in Antarctica (Vieira et al., 2010; Obu et al., 2020)). Ground ice volume in permafrost is variable, reaching up to 90% in syngenetic permafrost deposits (Kanevskiy et al., 2013; Gilbert et al., 2016). The SROCC (Meredith et al., 2019) reported *medium confidence* in the estimation that Earth's total perennial ground ice volume is equivalent to 2-10 cm of global sea level (Zhang et al., 2000). There is no evidence suggesting that a large part of this volume, if melted, would run off and contribute to global sea level. Therefore, and because of the modest total volume of mobilizable water, the contribution of permafrost thaw to past and future sea-level budgets is usually neglected (see section 9.6.3.2).

Permafrost changes mostly refer to changes in extent, temperature and active layer thickness. The SROCC (Hock et al., 2019b; Meredith et al., 2019) reported with *very high confidence* that record high permafrost temperatures at the depth of the zero annual amplitude (the depth about 10 to 20 m below the surface where the seasonal soil temperature cycle vanishes) were attained in recent decades in the Northern circumpolar permafrost region, *high confidence* that permafrost has warmed over recent decades in many mountain ranges, and overall *very high confidence* that global warming over the last decades has led to widespread permafrost warming. As reported in the SROCC, the global (polar and mountain) permafrost temperature has increased at 0.29 ± 0.12°C near the depth of zero annual amplitude between 2007 and 2016 (Biskaborn et al., 2019). Stronger warming has been observed in the continuous permafrost zone (0.39 ± 0.15°C) compared to the discontinuous zone (0.20 ± 0.10°C), consistent with the fact that near the melting point, a large amount of energy is required for melting the ice (Figure 9.22), and because of the reduced effect of Arctic amplification in more southerly locations (Romanovsky et al., 2017). This is consistent with longer-term Arctic trends from deep boreholes shown in Figure 2.22. Mountain permafrost temperature trends are heterogeneous, reflecting variations in local conditions such as topography, surface type, soil texture and snow cover, but again, generally weaker warming rates are observed in warmer permafrost at temperatures close to 0°C, particularly when ice content is high (e.g., Mollaret et al., 2019; Noetzli et al., 2019; PERMOS, 2019). In summary, strong variability in recent permafrost temperature trends is linked to local conditions, regionally varying temperature trends and the thermal state of permafrost itself, but as discussed in Section 2.3.2.5, there is overall *high confidence* in the observed increases in permafrost temperature over the past 3 to 4 decades throughout the permafrost regions.

Closer to the surface, the active layer undergoes annual cycles of freeze and thaw. The SROCC reported *medium confidence* in active layer thickness (ALT) increase as a pan-Arctic phenomenon. Recent evidence presented in Section 2.3.2.5 shows pervasive ALT increase in the European and Russian Arctic in the 21st century and in high elevation areas in Europe and Asia since the mid-1990s. Emergence of a clearer global picture is hampered by (1) uneven distribution of observing sites, (2) substantial variability among the existing sites, strongly influenced by local conditions (soil constituents and moisture, snow cover, vegetation); (3) interannual variability , and (4) thaw settlement in ice-rich terrain (Streletskiy et al., 2017; O'Neill et al., 2019). In summary, in agreement with the SROCC and recent evidence presented in Section 2.3.2.5, there is *medium confidence* that ALT increase is a pan-Arctic phenomenon.

There is *medium confidence* that the observed acceleration and destabilization of rock glaciers is related to warming temperatures and increase in water content at the permafrost table in recent decades (Deline et al., 2015; Cicoira et al., 2019; Marcer et al., 2019; PERMOS, 2019; Kenner et al., 2020). There is also *medium confidence* that observed increases in size and frequency of rock avalanches are linked to permafrost degradation in rock walls (Ravanel et al., 2017; Patton et al., 2019; Tapia Baldis and Trombotto Liaudat, 2019). In summary, there is *medium confidence* that mountain permafrost degradation at high altitude has increased the instability of mountain slopes in the past decade.

The SROCC assessed with *high confidence* that the extent of subsea permafrost, formed before submersion on Arctic continental shelves during the last deglaciation, is much reduced compared to older studies that had estimated the entire formerly exposed Arctic shelf area to be underlain by permafrost. This is supported by observations (Shakhova et al., 2017) that show rapid thaw of recently submerged permafrost on the East Siberian Shelf . A modelling study (Overduin et al., 2019) estimates that 97% of permafrost under Arctic

ACCEPTED VERSION SUBJECT TO FINAL EDITING

shelves is currently thinning.

Based on multiple studies, there is *medium confidence* that widespread retreat of coastal permafrost is accelerating in the Arctic (Günther et al., 2015; Cunliffe et al., 2019; Isaev et al., 2019). There is also consistent evidence of complete permafrost thaw in areas of discontinuous and sporadic permafrost since about 1980 (Camill, 2005; Kirpotin et al., 2011; James et al., 2013; Jones et al., 2016a; Borge et al., 2017; Chasmer and Hopkinson, 2017; Gibson et al., 2018a), but this evidence is geographically scattered. In spite of increasing evidence of landscape changes from site studies and remote sensing, quantifying permafrost extent change remains challenging because it is a subsurface phenomenon that cannot be observed directly (Jorgenson and Grosse, 2016; Trofaier et al., 2017). A modelling study for the Qinghai-Tibet Plateau between the 1960s and the 2000s (Ran et al., 2018) suggests transition from permafrost to seasonally frozen ground over an area of more than 400,000 km^2. In summary, there is *medium confidence* that complete permafrost thaw in recent decades is a common phenomenon in discontinuous and sporadic permafrost regions. In addition, paleoclimatic evidence presented in Section 2.3.2.5 confirms a long-term sensitivity of permafrost extent to climatic variations, although an analysis of North American speleothem records over the last two glacial cycles indicates that this apparent high sensitivity could be a consequence of regional-scale variability (Batchelor et al., 2019).

There is a lack of formal studies attributing observed permafrost changes (thaw depth, thermal state) or associated landscape changes to anthropogenic forcing. However, the observed Arctic warming has been attributed to anthropogenic forcing (e.g., Najafi et al., 2015) and an obvious physical link exists between ground temperatures (and thus permafrost) and surface air temperatures. Therefore physically consistent and convergent lines of evidence lead to *medium confidence* in anthropogenic forcing being the dominant cause of the observed pan-Arctic permafrost changes. Added to this, local permafrost change by soil and ecosystem disturbance is induced by increasing human industrial activities in the Arctic (e.g., Raynolds et al., 2014).

9.5.2.2 Evaluation of permafrost in climate models

As stated in AR5 (Flato et al., 2013), coupled models contributing to CMIP5 showed large inter-model variability of permafrost extent due to deficiencies in reproducing surface characteristics and processes (Koven et al., 2013), particularly thermal properties of the ground and snow. These deficiencies led the SROCC (Meredith et al., 2019) to express only *medium confidence* in the models' capacity to correctly project the magnitude of future permafrost changes, in spite of *high confidence* in the models' projection of a general thaw depth increase and a substantial loss of shallow permafrost. The SROCC further noted that several types of physical "pulse" disturbances, in particular fire and thermokarst formation, are usually not represented in coupled climate models. This has been discussed in detail in the SROCC, which assessed that there is *high confidence* that permafrost degradation through fire (Jones et al., 2015; Gibson et al., 2018b) is currently occurring faster in some well-studied regions than during the first half of the 20th century, and *medium confidence* that thermokarst formation, to which about 20% of the northern permafrost region is vulnerable (Olefeldt et al., 2016), can lead to faster large-scale permafrost degradation in response to climate change.

Since the SROCC, dedicated modelling of the evolution of ice- and organic-rich permafrost in the northeast Siberian lowlands (Nitzbon et al., 2020) has shown that not representing thermokarst-inducing processes in ice-rich terrain leads to a systematic underestimation of the rapidity and magnitude of permafrost thaw. Simplified inventory-based modelling (Turetsky et al., 2020) points towards similar conclusions. Although these pulse disturbances still need to be represented in CMIP-type models, there have been many new developments to that type of model since CMIP5 and the AR5. Soil freezing and its thermal and hydrological effects are now included in a large number of land-surface modules that are part of the CMIP6 ensemble (Chadburn et al., 2015a; Hagemann et al., 2016; Cuntz and Haverd, 2018; Guimberteau et al., 2018; Yokohata et al., 2020), sometimes allowing for the effects of excess ice (Lee et al., 2014). Improved representation of snow insulation in models has led to more realistic simulated permafrost extents (e.g., Paquin and Sushama, 2015). In a post-CMIP5 ensemble of land-surface models driven by observed

ACCEPTED VERSION SUBJECT TO FINAL EDITING

meteorological conditions (McGuire et al., 2016), inter-model spread was substantially reduced when the ensemble was restricted to models that appropriately represented the effect of snow insulation on the underlying soil (Wang et al., 2016b). More detailed descriptions of high-latitude vegetation characteristics, vegetation dynamics, and snow-vegetation interactions have been included in several models (Chadburn et al., 2015b; Porada et al., 2016; Druel et al., 2017) since the AR5.

A total soil column depth of at least about 10 m is required to adequately represent the dampening effect of seasonal-scale heat exchanges between shallow and deeper ground, and thus to correctly simulate active layer thickness (Lawrence et al., 2008; Ekici et al., 2015). However, many CMIP6 models still have shallower total soil columns (Burke et al., 2020) and the proportion of models with deeper total soil columns has not increased since CMIP5 (Koven et al., 2013). Another recently identified process, usually not represented in the current (CMIP6) generation of climate models (Zhu et al., 2019), is warming-driven decomposition and burning of organic material that provides strong thermal insulation of underlying ground. Decay of the insulating organic material can lead to increased permafrost thaw, creating a positive feedback loop.

In spite of the aforementioned structural improvements to many models, the simulated current permafrost extent from available CMIP6 models shows no substantial improvement with respect to CMIP5 (see Figure 9.22a). The extent of the region where permafrost is simulated within the top 15 m in the Northern Hemisphere for the 1979-1998 period is characterized by very large scatter in the coupled CMIP5 and CMIP6 historical simulations compared to estimates of the present permafrost extent based on multiple observational lines of evidence (Zhang et al., 1999) and models based on satellite observations and reanalyses (Gruber, 2012; Obu et al., 2019). Outliers with very low simulated permafrost extent are models that have only a very shallow soil column (leading to an underestimate of thermal inertia at depth) and do not take into account soil water phase changes. These inadequacies lead to an overestimate of seasonal thaw depth, exceeding the total thickness of the models' soil columns (Burke et al., 2020). Excessive simulated permafrost extent can in several cases be traced to insufficient thermal insulation by the winter snow cover (Burke et al., 2020).

Figure 9.22a also shows that the corresponding land-atmosphere simulations with prescribed observed sea-surface temperatures and sea-ice concentrations, and the land-only simulations with prescribed reanalysis-based meteorological forcing, do not provide an improved simulation of the current permafrost extent, although, by construction, they can be expected to exhibit lower land surface climate biases. This further points to deficiencies in the land modules as the main reason for biases, consistent with conclusions drawn from the analysis of CMIP5 output (Koven et al., 2013), as reported in the SROCC and the AR5.

In spite of more realistic description of permafrost-related processes in many coupled climate models, the CMIP6 models thus still produce a very scattered ensemble of estimates of current permafrost extent, and there is *high confidence* that this is strongly linked to deficiencies of the representation of soil processes. Furthermore, current-generation climate models tend to neglect several physical disturbances that can lead to faster permafrost thaw. Because of large uncertainties in the future evolution of these drivers (see SROCC), there is *limited evidence* that these shortcomings lead to an underestimate of permafrost degradation rates in response to climate change in the CMIP6 ensemble. In summary, there is *high confidence* that coupled models correctly simulate the sign of future permafrost changes linked to surface climate changes, but only *medium confidence* in the amplitude and timing of the transient response.

[START FIGURE 9.22 HERE]

Figure 9.22: Simulated versus observed permafrost extent and permafrost volume change by warming level. a) Diagnosed Northern Hemisphere permafrost extent (area with perennially frozen ground at 15 m depth, or at the deepest model soil level if this is above 15 m) for 1979-1998, for available CMIP5 and CMIP6 models, from the first ensemble member of the historical coupled run, and for CMIP6 AMIP (atmosphere+land surface, prescribed ocean) and land-hist (land only, prescribed atmospheric forcing) runs. Estimates of current permafrost extents based on physical evidence and reanalyses are indicated as black symbols (triangle: Obu et al. (2018); star: Zhang et al. (1999); circle: central value and associated

range from Gruber (2012)). b) Simulated global permafrost volume change between the surface and 3 m depth as a function of the simulated GSAT change, from the first ensemble members of a selection of scenarios, for available CMIP6 models. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.22 HERE]

9.5.2.3 Projected permafrost changes

The AR5 (Collins et al., 2013) and the SROCC (Meredith et al., 2019) (based on available CMIP5 output) both expressed *high confidence* that future pan-Arctic thaw depth will increase and near-surface permafrost extent will decrease under future global warming, and *medium confidence* in the magnitude of the simulated changes because of model deficiencies and large spread of the results.

The equilibrium sensitivity of permafrost extent to stabilized global mean warming has been inferred (by constraining CMIP5 output with diagnosed relationships between the observed present-day spatial distribution of permafrost and air temperature) to be about 4.0×10^6 km^2 °C^{-1} (Chadburn et al., 2017) for GSAT changes with respect to the present below about +3°C. This equilibrium permafrost sensitivity, relevant for assessing long-term permafrost changes at a stabilized warming level, is about 20% higher than the transient centennial-scale near-surface permafrost extent sensitivity (diagnosed from seasonal thaw down to 3 m depth) suggested by direct analysis of CMIP5 output (Slater and Lawrence, 2013). Compared to these and other studies reported in the AR5 and the SROCC (Koven et al., 2013), the recently suggested equilibrium extent sensitivity to GSAT changes of about 1.5×10^6 km^2 °C^{-1} based on idealized ground temperature modelling (Liu et al., 2021) appears unrealistically low.

A strong transient temperature sensitivity of the volume of perennially frozen soil in the top 3 m below the surface is consistently suggested by the available CMIP6 models (Figure 9.22b). Relative to the current volume, the transient sensitivity of the modelled permafrost volume in the top 3 m to GSAT changes (with respect to the 1995-2014 average and up to +3°C change, that is, about up to +4°C with respect to pre-industrial levels) is about 25 ± 5 % °C^{-1} (Burke et al., 2020), but there is only *medium confidence* in this value and 1s.d. uncertainty range because of the model deficiencies discussed in 9.5.2.2. It is important to note that permafrost loss will not be limited to the top 3 m, with delayed response of deeper permafrost. The simulated transient temperature sensitivity of permafrost volume is slightly stronger in the SSP1-2.6 scenario than in other SSPs because subsurface temperature lag increases with higher atmospheric warming rates, particularly when ground ice melting induces additional delays.

Due to the role of air temperature as a major driver of permafrost change, the SROCC (Hock et al., 2019b) expressed *very high confidence* that permafrost in high-mountain regions is expected to undergo increasing thaw and degradation during the 21st century, with stronger consequences expected for higher greenhouse gas emission scenarios. Recently published studies (e.g., Zhao et al., 2019) support this SROCC assessment.

In summary, based on *high agreement* across CMIP6 and older model projections, fundamental process understanding, and paleoclimate evidence, it is *virtually certain* that permafrost extent and volume will shrink as global climate warms.

9.5.3 Seasonal snow cover

Mean snow cover extent in January and February, the usual months of maximum extent, covers about 45% of the Northern Hemisphere (NH) land surface (more than 45 million km^2 over the 1967-2014 period (Estilow et al., 2015)). In contrast, maximum seasonal snow cover in South America, the dominant ice-free land mass in the Southern Hemisphere in terms of seasonal snow cover extent, remains well below 1 million km^2 (Foster et al., 2009) or less than 2% of the Southern Hemisphere land surface.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Terrestrial snow cover is characterized via three variables: (1) areal snow cover extent (SCE), (2) the time period of continuous snow cover (snow cover duration (SCD) which reflects snow-on and snow-off dates) and (3) snow accumulation expressed either as snow depth (SD) or snow water equivalent (SWE; the depth of water stored by the snowpack).

Observed large-scale snow cover changes, their attribution to human activity and their effects on the hydrological cycle are also discussed in Chapter 2 (Section 2.3.2.2), Chapter 3 (Section 3.4.2) and Chapter 8 (Section 8.2.3.1) of this report. The role of snow in the global surface albedo feedback is assessed in Section 7.4.2.3. The effect of aerosol deposition on snow albedo and associated climate forcing is assessed in Section 7.3.4.3.

9.5.3.1 Observed changes of seasonal snow cover

The AR5 (Vaughan et al., 2013) reported that NH SCE in June *very likely* decreased by 11.7% [8.8 to 14.6 %] per decade over the 1967-2012 period, exceeding the absolute and relative reductions observed in March and April. The AR5 further reported *very high confidence* that NH March and April SCE decreased over the 90 years after 1922. The SROCC only assessed snow cover changes for the Arctic and mountain areas. For the Arctic (north of 60°N), the SROCC (Meredith et al., 2019) expressed *high confidence* in SCE decreases of -3.5 ± 1.9% per decade in May and -13.4± 5.4% per decade in June, based on a combination of multiple datasets (Mudryk et al., 2017). Concerning mountain snow cover, the SROCC (Hock et al., 2019b) reported with *high confidence* that mountain snow cover (both in terms of SCE and maximum SWE) has generally declined since the middle of the 20th century at lower elevations. At higher elevations, the SROCC reported *medium confidence* in generally insignificant snow cover trends where these were available. The large-scale assessment provided in Section 2.3.2.2 of this report reports *very high confidence* in substantial reductions of NH snow cover extent (particularly in spring) since 1978, and states that there is *limited evidence* that this decline extends back to the early 20th century.

Since the SROCC, progress in characterizing seasonal NH snow cover changes has been made through the combined analysis of datasets from multiple sources (surface observations, remote sensing, land surface models and reanalysis products). A recent combined dataset (Mudryk et al., 2020) identified negative NH SCE trends in all months between 1981 and 2018, exceeding -50×10^3 km^{2}yr^{-1} in November, December, March and May (Figure 9.23a,b). The loss of spring SCE is also reflected in earlier spring snow melt, derived from surface observations (Bulygina et al., 2011; Brown et al., 2017), satellite observations (Wang et al., 2013; Estilow et al., 2015; Anttila et al., 2018), and model-based analyses (Liston and Hiemstra, 2011). There is considerable inter-dataset and regional variability, but the continental-scale trends of spring snow-off dates from these datasets are consistently negative (Brown et al., 2017; Kouki et al., 2019).

Satellite-derived estimates of NH SCE compiled within the NOAA snow chart Climate Data Record (NOAA CDR) extend back to 1967, providing one of the longest environmental data records from spaceborne measurements (Estilow et al., 2015). Continental trends from these coarse resolution estimates (~200 km) show declining snow cover during the spring period, consistent with surface warming (Hernández-Henríquez et al., 2015; Mudryk et al., 2017). As assessed in Section 2.3.2.2, there is therefore *very high confidence* that the NH spring SCE has been decreasing since 1978.

Hemispheric reconstructions with simple snow models and in-situ observations have extended the satellite record to 1922 (Brown and Robinson, 2011), putting the satellite era in historical context. This study, also assessed in the AR5, suggests an increase in North American spring (March-April) SCE from 1915 to about 1950, followed by a decrease of the same total magnitude afterwards. In Eurasia, a negative trend in April is visible over the entire 1922-2010 period of record, while in March, a step decrease at about 1985 separates two periods with insignificant trends. Overall, combining March and April, consistency between the continental trends since 1950 and agreement in sign with the NOAA satellite record since 1967 provides *high confidence* in Northern Hemisphere spring snow cover decrease since about 1950. Analysis of paleoclimate records (Pederson et al., 2011; Belmecheri et al., 2016) suggests that recent snowpack reductions in western North America are exceptional on a millennial timescale (*medium confidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Recent remote sensing global-scale studies (Hammond et al., 2018; Notarnicola, 2020) report that since 2000, snow cover area and/or duration decreased in 78% of global mountain areas (Notarnicola, 2020). Due to the shortness of these records and high spatial variability, they only provide *limited evidence* in *medium agreement* that snow cover area and duration changes over that recent period are more consistently negative at higher (>4000 m) than at lower elevations, and do not alter the *high confidence* in longer-term mountain snow cover decrease at lower elevations since the middle of the 20th century that was already reported in the SROCC.

As assessed in detail in Chapter 3 (Section 3.4.2), it is *very likely* that anthropogenic influence contributed to the observed reductions in Northern Hemisphere springtime snow cover since the mid-20th century. The reasons for this assessment are: (1) physical consistency of the observed spring snowpack and surface temperature changes both in observations and models, (2) the strong observed hemispheric and regional spring SCE and SWE trends, and (3) the general attribution of hemispheric temperature changes to human influence. Consistent between multiple observational products and historical climate model simulations, the observed NH SCE sensitivity to NH land (>30°N) warming (Mudryk et al., 2017) is approximately -1.9×10^6 km^2°C^{-1} (95% confidence range of $\pm 0.9 \times 10^6$ km^2 °C^{-1} throughout the snow season.

Compared to numerous studies on spring SCE changes, less attention has been paid to changes in NH snow cover during the onset period in the autumn, a challenging period to retrieve snow information from optical satellite imagery due to persistent clouds and decreased solar illumination at higher latitudes. Positive trends in October and November SCE in the NOAA-CDR (Hernández-Henríquez et al., 2015) are not replicated in other surface, satellite, and model datasets (Brown and Derksen, 2013; Peng et al., 2013; Hori et al., 2017; Mudryk et al., 2017). The positive trends from the NOAA-CDR are also inconsistent with later autumn snow-on dates since 1980 (-0.6 to -1.4 days per decade), based on historical surface observations, model-derived analyses and independent satellite datasets (updated from Derksen et al., 2017). Furthermore, the SCE trend sensitivity to surface temperature forcing in the NOAA-CDR is anomalous compared to other datasets during October and November (Mudryk et al., 2017). There is therefore *medium confidence* that the NH SCE trend for the 1981-2016 period was also negative during these two months (Mudryk et al., 2020).

In the low-to-mid latitude (18°S-40°S) South American Andes, a dry-season snow cover decrease of about 12% per decade has been reported for the period 1986-2018 (Cordero et al., 2019), linked to ENSO changes dominant in the northern part and an additional influence of poleward migration of the westerly wind zone in the southern part of the study area. Further South, long-term warming has been identified as the dominant cause of observed winter snow cover reduction over the 1972-2016 period at about 53°S in Brunswick Peninsula (Aguirre et al., 2018).

The AR5 (Hock et al., 2019b) reported on snow water equivalent (SWE) and snow depth (SD) in situ observations mostly from mountain areas, the majority of which showed negative trends over their respective observational periods. However, the AR5 did not provide an assessment of large-scale snow mass changes across the Northern Hemisphere. The SROCC attributed *medium confidence* to reports of negative SWE trends in the Russian Arctic between 1966 and 2014, and stated that seasonal maximum snow depth trends in the North American Arctic were mostly insignificant and of inconsistent sign. It further attributed *medium confidence* to gridded products that suggest negative pan-Arctic SWE trends between 1981 and 2016, and *high confidence* in a general decline of mountain snow mass at lower elevations, albeit with regional variations.

Since the AR5, the number of global or hemispheric-scale gridded SWE products has substantially increased. A validation and intercomparison (Mortimer et al., 2020) of datasets derived from (1) reanalysis-based products, (2) a combined surface observation – passive microwave remote sensing product and (3) stand-alone passive microwave products has led to better understanding of the strengths and limitations of each. These gridded products consistently identify negative trends in maximum pre-melt SWE over the 1981 – 2016 period over both Eurasia and North America (Mudryk et al., 2020); (Figure 9.23c and d). To further constrain SWE uncertainty, Pulliainen et al. (2020) implemented a bias correction based on snow course observations which yielded a current best estimate for the average 1980-2018 March SWE over NH non-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

alpine land north of 40°N of 2938 Gt [*likely* range 2846-3062 Gt]. Using this method, the bias-corrected GlobSnow3.0 dataset suggests a 4.6 Gt yr^{-1} decrease of March SWE over this 39-year period across North America, and a negligible trend across Eurasia. These SWE trends are consistent with the continental SCE trends over this period as assessed above, but strong regional and temporal variability only allows *medium confidence* in the signs and magnitudes of these trends. However, there is *high confidence* in a general decline of NH spring SWE since 1981 (Section 2.3.2.2). In the longer term (see also Section 2.3.2.2), annual maximum snow depth trends from site measurements confirm mostly negative trends in North America (Kunkel et al., 2016) between 1960/61 and 2014/15 and strong spatial variability in Eurasia (Zhong et al., 2018) between 1966 and 2012, with spatial patterns bearing some resemblance to the shorter satellite-based trends reported by Pulliainen et al. (2020). However, over this longer period, the Eurasian measurements (Zhong et al., 2018) exhibit, on average, a positive trend. On the Qinghai–Tibetan Plateau, site measurements between 1961 and 2010 (Xu et al., 2017) suggest a shift from an initial increase of spring snow depth until about 1980 to a decreasing trend afterwards.

[START FIGURE 9.23 HERE]

Figure 9.23: Observed monthly Northern Hemisphere (a) snow cover trends and (b) anomalies, and (c) snow mass trends and (d) anomalies. From the observation-based ensemble discussed in the text (Mudryk et al., 2020). Trends and anomalies are calculated over the 1981-2018 period. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.23 HERE]

Concerning the assessment of SWE trends in mountainous regions, the SROCC noted a need for observations spanning several decades because of very strong temporal variability. Moreover, determining SWE trends in mountain regions is challenging because the coarse resolution (typically 25 to 50 km) of gridded SWE products is inadequate in areas of mountainous terrain (Snauffer et al., 2016). Based on a compilation of a large number of studies of SWE trends in mountain regions, the SROCC noted strong regional variations, but a general consistency in greater reductions in SWE at lower elevations associated with shifts from solid to liquid precipitation. A recent synthesis of snow observations in the European Alps (Matiu et al., 2021) shows a 1971-2019 seasonal (November to May) snow depth trend of -8.4% per decade, along with negative maximum snow depth and seasonal snow cover duration trends. The trends are stronger and more significant during transitional seasons and at transitional (from no snow to snow) altitudes, and exhibit strong regional variations, consistent with earlier reports for the Swiss and Austrian Alps (Schöner et al., 2019) and the Pyrenees (López-Moreno et al., 2020).

In summary, since the AR5, intercomparison, dataset blending of gridded products, and bias correction using snow course measurements contributed to an improved estimate of the average 1980-2018 March SWE over NH non-alpine land north of 40°N of 2938 Gt [*likely* range 2846-3062 Gt], with *medium confidence* in the magnitudes of continental-scale trends over that period. However, there is *high confidence* in a general decline of NH spring SWE since 1981 (Section 2.3.2.2). In mountain areas, in situ observations tend to suggest that annual maximum SWE reductions are generally stronger at elevation bands where shifts from solid to liquid precipitation affected the snow mass.

9.5.3.2 Evaluation of seasonal snow in climate models

Building on the AR5 (Flato et al., 2013) and subsequent published work, the SROCC (Meredith et al., 2019) stated that CMIP5 models tended to underestimate the observed decrease of Northern Hemisphere spring snow cover extent due to inappropriate parameterisation of snow processes, misrepresentation of the snow-albedo feedback, underestimated temperature sensitivity, and biased climatological spring snow cover. Since the AR5, progress in the observation, description and understanding of snow microstructure (Kinar and Pomeroy, 2015; Calonne et al., 2017) and its links to physical (thermal and radiative) properties (Löwe et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2013; Calonne et al., 2014) has prompted efforts to represent physical properties as a function of the evolving snow microstructure in models (Carmagnola et al., 2014; Calonne et al., 2015). However, even state-of-the-art snow models intended for meteorological and climate applications still struggle to correctly represent the time evolution of the snow thermal properties, particularly of cold and dry tundra snow (Domine et al., 2016). Moreover, most, if not all, CMIP6 climate models do not explicitly represent the darkening of snow by deposition of BC and other light-absorbing aerosol species that is known to influence snow melt rates (Section 7.3.4.3). Regardless of these shortcomings, snow modules of climate models continue to be improved. Recent progress includes the incorporation of multiple energy balances within the canopy and between subgrid-tiles with different snow heights (Aas et al., 2017; Boone et al., 2017) and inclusion of advanced specific snow models in coupled climate models (Niwano et al., 2018; Voldoire et al., 2019), opening the prospect of future progress in quantifying snow-related feedbacks in a changing climate. Recently developed multi-physics snow models (Essery, 2015; Lafaysse et al., 2017), which are able to emulate the behaviour of a large number of models in a broad range of climates, allow model shortcomings and key parameter uncertainties, for example, concerning snow masking by vegetation or snow thermal conductivity, to be identified. Guidance for future model improvement can be provided by improved diagnostics, such as a concise metric of snow insulation (Slater et al., 2017a), which builds on an observed relation between effective seasonal mean snow depth and the dampening of winter season temperature decrease within the soil, and allows an efficient quantification of inaccuracies in the simulated snow insulation effect.

There is *high confidence* that large inter-model variations in the snow-cover sensitivity to temperature can largely be explained by inaccuracies in the simulated snow albedo feedback (Qu and Hall, 2014); a multi-model sub-ensemble of CMIP5 models that simulate a correct magnitude of this feedback presents a 40% reduced spread in the projected 21st century Northern Hemisphere land warming trend (Thackeray and Fletcher, 2016). Errors of the simulated feedback strength were linked to 1) systematic positive albedo biases over the boreal forest belt, mostly due to unrealistic treatment of vegetation masking (Thackeray and Fletcher, 2016), 2) inaccurate prescribed tree cover fraction and inappropriate parameterization of leaf area index in some models (Loranty et al., 2014; Wang et al., 2016a) and 3) low spatial resolution leading to inaccuracies in the strength of the simulated SAF in mountainous regions (Letcher and Minder, 2015). Although the representation of snow albedo feedback improved in many CMIP5 models over CMIP3, some models deteriorated (Thackeray et al., 2018).

Analysis of the available CMIP6 historical simulations for the 1981-2014 shows that on average, CMIP6 models simulate well the observed SCE (Mudryk et al., 2020), except for outliers and a median low bias during the winter months (Figure 9.24a). This is an improvement over CMIP5 (Mudryk et al., 2020), in which many snow-related biases were linked to inadequacies of the vegetation masking of snow cover over the boreal forests (Thackeray et al., 2015). A comparison between CMIP5 and CMIP6 results (Mudryk et al., 2020) shows that there is no notable progress in the quality of the representation of the observed 1981-2014 monthly snow cover trends.

[START FIGURE 9.24 HERE]

Figure 9.24: Simulated CMIP6 and observed snow cover extent (SCE). a) Simulated CMIP6 and observed (Mudryk et al., 2020) SCE (in millions of km^2) for 1981-2014. Boxes and whiskers with outliers represent monthly mean values for the individual CMIP6 models averaged over 1981-2014, with the red bar indicating the median of the CMIP6 multi-model ensemble for that period. The observed interannual distribution over the period is represented in green, with the yellow bar indicating the median. b) Spring (March to May) Northern Hemisphere snow cover extent against GSAT (relative to the 1995-2014 average) for the CMIP6 Tier 1 scenarios (SSP1-2.6, SSP2-4.5, SSP3-7.0 and SSP5-8.5), with linear regressions. Each data point is the mean for one CMIP6 simulation (first ensemble member for each available model) in the corresponding temperature bin. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

9.5.3.3 Projected snow cover changes

The AR5 (Collins et al., 2013) stated that substantial NH spring snow cover reductions at the end of the 21st century were *very likely* under strong emission scenarios, and expressed *medium confidence* in the projected geographic patterns of annual maximum SWE changes. Based on studies using downscaled CMIP5 or RCM output, either directly or via snowpack models driven by such output, the SROCC (Hock et al., 2019b) reported *likely* snow depth or mass decreases at lower elevations in many mountain ranges over the 21st century and *high confidence* in smaller future changes at higher elevations.

Since the AR5, one study (Brown et al., 2017), applying a method developed by de Elía et al. (2013) to a CMIP5 sub-ensemble, suggested that over most of the Northern Hemisphere, the projected decrease of SCD will exceed natural variability before this will be the case for annual maximum SWE. The same study reports that over large parts of Eastern and Western North America and Europe, forced SCD changes are projected to exceed natural variability in the 2020s both in spring and autumn, while the signals tend to emerge later in the Arctic regions and particularly late, after 2060, in Eastern Siberia under the RCP8.5 scenario. Thackeray and Fletcher (2016) have shown that inter-model spread in projected spring SCE trends could be reduced through improved simulation of spring season warming because of the tight coupling between temperature and SCE linked to the snow albedo feedback (Qu and Hall, 2014; Thackeray and Fletcher, 2015).

Across all emission scenarios and with negligible scenario dependence (Figure 9.24b), CMIP6 models consistently (all models and all months) simulate Northern Hemisphere snow cover decrease in response to future GSAT change over the 21st century (Mudryk et al., 2020). The simulated SCE decrease is close to a linear function of global temperature change for all months (shown in Figure 9.24b for spring, with *medium confidence* in an average sensitivity of about -8% per °C of GSAT increase), except when snow cover vanishes. This occurs at about +2°C of GSAT change above the 1995-2014 level (that is, about +3°C above the pre-industrial level) for the months of July and August, and at about +3°C above the 1995-2014 level for June and September. Possible effects of such changes on the hydrological cycle are assessed in Chapter 8 (Section 8.2.3.1).

In summary, consistent projections from all generations of global climate models, elementary process understanding and strong covariance between snow cover and temperature on several time scales make it *virtually certain* that future Northern Hemisphere snow cover extent and duration will continue to decrease as global climate continues to warm, and process understanding strongly suggests that this also applies to Southern Hemisphere seasonal snow cover (*high confidence*).

Seasonal snow cover, by definition, has a clear annual cycle with usually complete disappearance in spring and summer and re-formation in autumn or winter. Therefore, there is *very high confidence* that the current and projected changes to seasonal snow cover are reversible (Verfaillie et al., 2018). In the case of global or regional cooling, abrupt large-scale snow-cover changes with a transition from seasonal to persistent snow cover due to a strong snow albedo feedback are a typical feature of glacial inceptions (e.g., Baum and Crowley, 2003; Calov et al., 2005), and these can be irreversible on centennial or longer timescales because of this feedback. In summary, based on physical understanding and the absence of occurrence of such events in climate model projections, abrupt future changes of seasonal snow cover on large scales in the absence of concomitant abrupt atmospheric change as a driver appear *very unlikely* in the context of current and projected warming.

9.6 Sea Level Change

9.6.1 Global and regional sea-level change in the instrumental era

9.6.1.1 Global mean sea-level change budget in the pre-satellite era

The SROCC (Oppenheimer et al., 2019) discussed the development and application of new statistical methodologies for reconstructing global mean sea level (GMSL; Box 9.1) from tide-gauge data over the 20th

ACCEPTED VERSION SUBJECT TO FINAL EDITING

century. Based on an ensemble of tide gauge reconstructions, the SROCC assessed an average rate of GMSL rise of 1.38 mm yr^{-1} [0.81 to 1.95 *very likely* range] for the period 1901 to 1990. Since the SROCC, two new GMSL reconstructions have been published (Dangendorf et al., 2019; Frederikse et al., 2020b) and are included in an updated ensemble estimate of GMSL change (Palmer et al., 2021, Section 2.3.3.3). Based on these updated data and methods, the GMSL change over the (pre-satellite) period 1901 to 1990 is assessed to be 0.12 m [0.07 to 0.17 *very likely* range] with an average rate of 1.35 mm yr^{-1} [0.78 to 1.92 *very likely* range] (*high confidence*) (Table 9.5; section 2.3.3.3) in agreement with the SROCC assessment. Both this assessment and SROCC have substantially larger uncertainties than the AR5 assessment, which was based upon a single tide gauge reconstruction and did not account for structural uncertainty (see Palmer et al., (2021) for a discussion).

The SROCC found that four of the five available tide gauge reconstructions that extend back to at least 1902 showed a robust acceleration (*high confidence*) of GMSL rise over the 20th century, with estimates for the period 1902-2010 (-0.002 to 0.019 mm yr^{-2}) that were consistent with the AR5. New tide gauge reconstructions published since the SROCC (Dangendorf et al., 2019; Frederikse et al., 2020b) support this assessment and suggest that increased ocean heat uptake related to changes in Southern Hemisphere winds and increased mass loss from Greenland are the primary physical mechanisms for the acceleration (section 2.3.3.3). Therefore, the SROCC assessment on the acceleration of GMSL rise over the 20th century is maintained.

The evaluation of the sea-level budget presented here, and in section 9.6.1.2, draws on assessments of the individual components (Section 2.3.3.1 and 9.2.4.1 for global-mean thermosteric and sections 9.5.1.1, 9.4.1.1 and 9.4.2.1 for ice mass loss contributions to GMSL change from glaciers and ice sheets). Following the approach of the SROCC, the mass loss from ice sheet peripheral glaciers is included in the ice sheet contributions to GMSL change (glacier mass loss from regions 5 and 19 of the Randolph Glacier Inventory 6.0 (RGI Consortium, 2017) are added to ice sheet mass loss where applicable, with uncertainties added in quadrature). The total change in GMSL for each component, and their sum, is summarised in Table 9.5 (uncertainties added in quadrature). For consistency across the report and to simplify the treatment of uncertainties, all budget calculations are based on the difference between the first and last year in each period (Palmer et al., 2021), rather than a linear fit to the underlying time series as used in SROCC and AR5.

The sea-level budget in the SROCC included the anthropogenic contribution of land water storage (LWS; Box 9.1) change from a single estimate (Wada, 2016). Since the SROCC, two studies have combined estimates of natural LWS change with anthropogenic LWS changes from reservoir impoundment and groundwater depletion (Cáceres et al., 2020; Frederikse et al., 2020b). For (Cáceres et al., 2020), zero change is assumed for the period 1901-1948, since their LWS change estimates are not available before 1948. Given the large year-to-year changes associated with hydrological variability, the assessed changes in LWS (Table 9.5) are based on linear trends for each period, following (Palmer et al., 2021). Structural uncertainty is estimated from the standard deviation of the trends across the two studies and parametric uncertainty is estimated based on the Monte Carlo simulations of (Frederikse et al., 2020b). These two sources of uncertainty are combined in quadrature and the assessed central estimate is taken as the average of the ensemble mean trends. Compared to the SROCC assessed LWS trend of -0.12 mm yr^{-1} for the period 1901-1990, the updated assessment leads to a more negative trend of -0.16 [-0.35 to 0.04] mm yr^{-1}, although the two are consistent within the estimated uncertainties. Previous studies and the SROCC have highlighted the large uncertainty in estimates of LWS change over the 20th century (Gregory et al., 2013), and therefore the SROCC assessment of *low confidence* in the estimated LWS contribution to GMSL change is maintained.

Since the SROCC, a new ocean heat content reconstruction (Zanna et al., 2019b) (Section 2.3.3.1) has allowed global thermosteric sea-level change to be estimated over the 20th century. As a result, the sea-level budget for the 20th century can now be assessed for the first time. For the periods 1901 to 1990 and 1901 to 2018 the assessed *very likely* range for the sum of components is found to be consistent with the assessed *very likely* range of observed GMSL change (*medium confidence*), in agreement with (Frederikse et al., 2020b) (Table 9.5). This represents a major step forward in the understanding of observed GMSL change over the 20th century, which is dominated by glacier (52%) and Greenland ice sheet mass loss (29%) and the effect of ocean thermal expansion (32%), with a negative contribution from the land water storage change (-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

14%). While the combined mass loss for Greenland and glaciers is consistent with the SROCC, updates in the underlying datasets lead to differences in partitioning of the mass loss.

9.6.1.2 Global mean sea-level change budget in the satellite era

The SROCC (Oppenheimer et al., 2019) concluded that GMSL increased at a rate of 3.16 [2.79 to 3.53 *very likely* range] mm yr^{-1} in the period 1993 to 2015 (the satellite altimetry era) and a rate of 3.58 [3.10 to 4.06 *very likely* range] mm yr^{-1} in the period 2006 to 2015 (the GRACE/Argo era) (*high confidence*). An updated assessment for the periods 1993 to 2018 and 2006 to 2018 yields values of 3.25 [2.88 to 3.61] and 3.69 [3.21 to 4.17] mm yr^{-1} (*high confidence*) (Table 9.5), with the slightly larger central estimates consistent with the observed acceleration in GMSL rise since the late 1960s (Dangendorf et al., 2019), given the longer assessment periods. Based on the GMSL assessed time series presented in section 2.3.3.3, GMSL acceleration is estimated as 0.075 [0.066 to 0.080] mm yr^{-2} for 1971 to 2018 and 0.094 [0.082–0.115] mm yr^{-2} for 1993–2018 (*high confidence*). For the common period of 1993-2010, the assessed rate of GMSL rise based on tide gauge reconstructions (3.19 [1.18 to 5.20] mm yr^{-1}) is consistent with the assessment based on satellite altimetry (2.77 [2.26 to 3.28] mm yr^{-1}), within the estimated uncertainties.

Since the SROCC, two new estimates of the LWS contribution have been published (Cáceres et al., 2020; Frederikse et al., 2020b) (see Section 9.6.1.1). For the early 21st century (the periods 1993 to 2018 and 2006 to 2018) both publications find a positive LWS contribution (Table 9.5), based on the most recent GRACE-derived estimates. This contrasts with the negative LWS contribution presented for the same periods in the SROCC based on (WCRP Global Sea Level Budget Group, 2018b) and reinforces the *low confidence* assessment of the LWS contribution.

For both periods in the satellite era, i.e., 1993 to 2018 and 2006 to 2018, the sum of contributions is consistent with the total observed GMSL change (*high confidence*) (Table 9.5). However, the latter period, which is characterised by improved data quality and coverage associated with satellite and Argo observations, shows much closer agreement in the central estimates. The marginal sea-level budget closure for the period 1993 to 2018 may indicate underestimated uncertainty, which may be structural as well as parametric. The sea-level budget assessments across the various periods in Table 9.5 demonstrate that the acceleration in GMSL rise (Section 2.3.3.3) since the late 1960s is mostly the result of increased ice sheet mass loss. However, all contributions to GMSL rise show their largest rate during 2006 to 2018, with the ice sheets accounting for about 35% of the total change during this period.

[START TABLE 9.5 HERE]

Table 9.5: Observed contributions to global mean sea level (GMSL) change for five different periods. Values are expressed as the total change (Δ) in the annual mean or year mid-point value over each period (mm) along with the equivalent rate (mm yr^{-1}). The *very likely* ranges appear in brackets based on the various section assessments as indicated. Uncertainties for the sum of contributions are added in quadrature, assuming independence. Percentages are based on central estimate contributions compared to the central estimate of the sum of contributions.

$^{T, A}$ and $^{T\&A}$ indicate assessments based on tide gauge reconstructions (T), satellite altimetry (A), or a combination of both (T&A). The assessment uses tide gauge reconstructions before 1993 and satellite altimetry after 1993.
*For the periods 1971-2018, 1993-2018, 2006-2018 and 1901-2018 the Caceres et al. (2020) linear trends are based on the period up to 2016.

[END TABLE 9.5 HERE]

9.6.1.3 Regional sea-level change in the satellite era

Regional sea-level changes are resolved by both tide gauge and satellite altimetry observations (Hamlington et al., 2020a). Altimeters have the advantage of quasi-global coverage but are limited to a period (1993-present) in which the forced trend response is just emerging on regional scales (Section 9.6.1.4). An analysis of the local altimetry error budget to estimate 90% confidence intervals on regional sea-level trends and accelerations reports that 98% of the ocean surface has experienced significant sea-level rise over the satellite era (Prandi et al., 2021). The same study finds that sea-level accelerations display a less uniform pattern, with an east/west dipole in the Pacific, a north/south dipole in the Southern Ocean and in the North Atlantic, and 85% of the ocean surface experiencing significant sea-level acceleration or deceleration, above instrumental and post processing noise. Longer records are available from tide gauges, albeit with variable coverage by basin. Regional departures from GMSL rise are primarily driven by ocean transport divergences that result from wind stress anomalies and spatial variability in atmospheric heat and freshwater fluxes (Section 9.2.4).

The SROCC (Oppenheimer et al., 2019) noted the occurrence of large multiannual sea-level variations in the Pacific, associated with the Pacific Decadal Oscillation (PDO) in particular, and involving the El Niño Southern Oscillation (ENSO), North Pacific Gyre Oscillation (NPGO) and Indian Ocean Dipole (IOD) (Annex IV) (Royston et al., 2018; Hamlington et al., 2020b). There was intensified sea-level rise during the 1990s and 2000s, with 10-year trends exceeding 20 mm yr^{-1} in the western tropical Pacific Ocean, while sea-level trends were negative on the North American west coast. During the 2010s, the situation reversed, with western Pacific sea level falling at more than 10 mm yr^{-1} (Hamlington et al., 2020b). For the Atlantic Ocean,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the SROCC described regional sea-level variability as being driven primarily by wind and heat flux variations associated with the North Atlantic Oscillation (NAO) and heat transport changes associated with AMOC variability. During periods of subpolar North Atlantic warming, winds along the European coast are predominantly from the south and may communicate steric anomalies onto the continental shelf, driving regional sea-level rise, with the reverse during periods of cooling (Chafik et al., 2019). High rates of sea-level rise in the North Indian Ocean are accompanied by a weakening summer South Asian monsoon circulation (Swapna et al., 2017).

The Arctic ocean is typically excluded from global sea-level studies, owing to the uncertainties associated with resolving sea-level in ice-covered regions, strong variations in GRD effects, and uncertain GIA estimates (Box 9.1). Spanning 1991-2018, a *very likely* sea-level riseof 1.16-1.81 mm yr^{-1} is observed (Rose et al., 2019). Since the SROCC, the forced response in regional sea level varies in time with the relative influence of different forcing agents (Fasullo et al., 2020).

The SROCC estimated regional sea-level changes from combinations of the various contributions to sea-level change from CMIP5 climate model outputs, allowing comparison with satellite altimeter and tide-gauge observations. Closure of the regional sea-level budget is complicated by the fact that regional sea-level variability is larger than GMSL variability and there are more processes that need to be considered, such as vertical land movement and ocean dynamical changes (Box 9.1). A number of observation-based studies have focussed on specific areas, such as the Mediterranean (García et al., 2006), the South China Sea (Feng et al., 2012), the US east coast (Frederikse et al., 2017; Piecuch et al., 2018), the North Atlantic basin (Kleinherenbrink et al., 2016) and the Northwestern European continental shelf seas (Frederikse et al., 2016). Studies using tide gauge data and observation-based estimates of the contributions find that, while local agreement is not yet possible, the observational sea-level budget can be closed on a basin scale (Slangen et al., 2014a; Frederikse et al., 2016, 2018, 2020b). A budget analysis for the GRACE era found that the budget closes in some but not all coastal regions: substantial parts of the sea-level change signal in the North Atlantic could not be explained by steric or barystatic changes (Rietbroek et al., 2016). This is in agreement with other work comparing climate model estimates to 20th century tide gauge observations (Meyssignac et al., 2017), where the majority of local spatial variability is determined by the ocean dynamic component. Vertical land movement is another major cause of local spatial variability in sea-level change, and for instance relevant for oceanic islands (Forbes et al., 2013; Martínez-Asensio et al., 2019). In summary, the regional sea-level budget, using either observations or models, can currently only be closed on basin scales (*medium confidence*), with large uncertainties remaining on smaller scales.

9.6.1.4 Attribution and time of emergence of regional sea-level change

The SROCC (Oppenheimer et al., 2019) attributed anthropogenic forcing to be the dominant cause of GMSL rise since 1970 (see also Section 3.5.3.2), but detection and attribution (Cross-Working Group Box: Attribution in Chapter 1) of 20th century externally forced regional sea-level changes is more challenging, as regional variability is larger (Section 9.6.1.3), and therefore the signal-to-noise ratio is smaller (Richter and Marzeion, 2014; Monselesan et al., 2015; Palanisamy et al., 2015). Whereas SROCC assessed with *high confidence* that GMSL rise is attributable to anthropogenic greenhouse gas emissions, they assessed with *medium confidence* that the regional anomalies in ocean basins are a combination of the response to anthropogenic GHG emissions and internal variability.

The simulated ocean dynamic and thermosteric response to external forcings during 1861-2005 is larger than simulated internal variability only in the Southern Ocean and North Pacific on a 1° grid (Slangen et al., 2015), but on spatial scales exceeding 2000 km a detectable signal is revealed in the last 45 years in 63% of the global ocean area (Richter et al., 2017). The thermosteric change in the upper 700 m in the period 1970-2005 shows similar observed and simulated forced geographical patterns, and anthropogenic forcing accounts for part (North Atlantic, 65%) or all (tropical Pacific, Southern Ocean) of the observed regional-mean (Marcos and Amores, 2014). The influences of greenhouse gases and anthropogenic aerosols can be partially distinguished by considering geographical or vertical ocean temperature variations (Slangen et al., 2015; Bilbao et al., 2019; Fasullo et al., 2020). Zonal-mean forced ocean dynamic sea-level change alone is

ACCEPTED VERSION SUBJECT TO FINAL EDITING

not detectable but, using spatial correlation, the global geographical pattern during the altimeter period is detectable in sea-level trends (Fasullo and Nerem, 2018). This pattern may already or will soon be detectable in individual years, based on an analysis of CMIP5 climate model simulations (Bilbao et al., 2015). Anthropogenic forcing, dominated by greenhouse gases, has strengthened the meridional sea-level gradient in the Southern Ocean since the 1960s (Slangen et al., 2015; Bilbao et al., 2019; Fasullo et al., 2020). New evidence finds that observed zonal-mean total sea-level trends during 1993 to 2018 in all basins are inconsistent with unforced variability alone and consistent with the modelled response to external forcing (Richter et al., 2020).

A region that has been studied intensely in the context of sea-level detection and attribution is the tropical Pacific. Observed sea-level trends in the tropical Pacific show a PDO-like (Annex IV) East-West dipole (with a greater rate of rise in the west, see section 9.6.1.3). This dipole does not occur in CMIP5 simulations with the magnitude and duration that was observed in the 1990s and 2000s, neither in response to historical forcing, nor as internal variability after removing the variability associated with the PDO (Bilbao et al., 2015). (Hamlington et al., 2014) did obtain a residual trend pattern for 1993-2010 in the tropical Pacific that may link to anthropogenic warming of the tropical Indian Ocean. Allowing for PDO and ENSO variations, (Royston et al., 2018) describe patches of the Pacific Ocean where the sea-level trend for 1993-2015 is distinguishable from temporally correlated noise. The acceleration in eastern Pacific sea-level rise is largely accounted for by variations resembling PDO and ENSO (Hamlington et al., 2020a).

In the future, the anthropogenic signal in regional sea-level change from ocean density and dynamics is projected to emerge first in regions with relatively small internal variability, such as the tropical Atlantic Ocean and the tropical Indian Ocean (Jordà, 2014; Lyu et al., 2014; Richter and Marzeion, 2014; Bilbao et al., 2015). The signal is projected to emerge over 50% of the ocean area by the 2040s (Lyu et al., 2014), but in regions where variability is large and projected changes are small, such as the Southern Ocean, the signal will not emerge before late in the century. Adding the projected sea-level change from land ice mass loss and groundwater extraction strengthens and modifies the forced signal, leading to times of emergence 10-20 years earlier in most parts of the ocean, except in regions close to sources of mass loss, with emergence over 50% of the ocean area by 2020 and nearly everywhere by 2100 (Lyu et al., 2014; Richter et al., 2017) (*medium confidence*).

In summary, detection of forced regional changes for some ocean areas in recent decades is possible *(medium confidence)*, but attribution of regional sea-level change to forcings over longer periods (20th century) and for all ocean basins isnot yet possible.

Cross-Chapter Box 9.1: Global energy inventory and sea level budget

Coordinators: Matthew D. Palmer (UK), Aimée B.A. Slangen (The Netherlands),

Contributors: Guðfinna Aðalgeirsdóttir (Iceland), Fábio Boeira Dias (Finland/Brazil), Catia M. Domingues (Australia/Brazil), Gerhard Krinner (France), Johannes Quaas (Germany), Lucas Ruiz (Argentina)

Increased atmospheric greenhouse gas emissions since the 19th century have led to a net positive radiative forcing of Earth's climate (Sections 2.2, 7.3) and a corresponding accumulation of energy in the Earth System. Quantification of this energy gain is essential to our understanding of observed climate change and for estimates of climate sensitivity (Section 7.5). The global energy inventory is closely linked to our understanding of observed global sea-level change, through the energy associated with loss of land-based ice and the effect of thermal expansion associated with ocean warming (Box 9.1, Sections 2.3.3.1, 9.6.1; Table 9.5).

The Earth System gained substantial energy over the period 1971-2018 (*high confidence*), with an assessed *very likely* range of 325 to 546 ZJ or 0.43 to 0.72 W m^{-2} expressed per unit area of the Earth's surface

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Cross-Chapter Box 9.1, Figure 1a; Section 7.2, Box 7.2). Ocean warming dominates the energy inventory change (*high confidence*), accounting for 91% of the observed energy increase for the period 1971-2018, with upper ocean warming (0-700 m) accounting for 56% (Section 7.2). Much smaller amounts went into melting of ice (3%) and heating of the land (5%) and atmosphere (1%). Overall, the percentage contributions are similar to those reported in IPCC AR5 for the period 1971-2010 (Rhein et al., 2013).

The observed global mean sea-level (GMSL) budget is assessed through comparison of the sum of individual components of GMSL change with independent observations of total GMSL change from tide gauge and satellite altimeter observations (Cross-Chapter Box 9.1, Figure 1b; Sections 2.3.3, 9.6.1; Table 9.5). The assessed sum of the observed components indicates that GMSL *very likely* increased by 72 to 117 mm over the period 1971-2018 (Table 9.5), with the largest contributions from ocean thermal expansion (50%) and melting of ice sheets and glaciers (42%). The assessed total GMSL change (Section 2.3.3) for the period 1971-2018 has a *very likely* range of 73-146 mm and as a result the sea-level budget is closed for this period (Cross-Chapter Box 9.1, Figure 1b, Section 9.6.1, Table 9.5).

The sea-level budget closure demonstrates improved quantification of the processes of observed GMSL change for this period relative to previous IPCC assessments (Church et al., 2013a; Oppenheimer et al., 2019). A related assessment presented in Chapter 7 demonstrates closure of the global energy budget (*high confidence*) (Box 7.2) and strengthens the confidence in scientific understanding of both of these key aspects of climate change.

[START CROSS-CHAPTER BOX 9.1, FIGURE 1 HERE]

Cross-Chapter 9.1, Figure 1: Global Energy Inventory and Sea Level Budget. a) Observed changes in the global energy inventory for 1971-2018 (shaded time series) with component contributions as indicated in the figure legend. Earth System Heating for the whole period and associated uncertainty is indicated to the right of the plot (red bar = central estimate; shading = *very likely* range); b) Observed changes in components of global mean sea-level for 1971-2018 (shaded time series) as indicated in the figure legend. Observed global mean sea-level change from tide gauge reconstructions (1971-1993) and satellite altimeter measurements (1993-2018) is shown for comparison (dashed line) as a 3-year running mean to reduce sampling noise. Closure of the global sea-level budget for the whole period is indicated to the right of the plot (red bar = component sum central estimate; red shading = *very likely* range; black bar = total sea level central estimate; grey sharing = *very likely* range). Full details of the datasets and methods used are available in Annex I. Further details on energy and sea-level components are reported in Table 7.1 and Table 9.5.

[END CROSS-CHAPTER BOX 9.1 HERE]

9.6.2 Paleo context of global and regional sea-level change

As the SROCC (Oppenheimer et al., 2019) noted, paleo-sea level records provide information on past ice-sheet changes, and process-based ice sheet models of past warm periods inform equilibrium responses. However, given uncertainties in paleo-sea level and polar paleoclimate and limited temporal resolution of paleo-sea level records, there is *low confidence* in the utility of paleo-sea level records for quantitatively informing near-term GMSL change. Nonetheless the paleo record does contextualise sea level and can test projection models (see also FAQ 1.3). Proxy constraints on GMSL and global ice volume are assessed in Sections 2.3.2.4. and 2.3.3.3 (see also FAQ 9.1). This section updates prior assessments of drivers of past GMSL changes and climatically coherent areas of relative sea-level variability. GMSL changes are framed in terms of GMST but noting that amplified high latitude warming is a robust equilibrium response to elevated CO_2 (Masson-Delmotte et al., 2013): polar air temperatures during past warm periods were up to twice the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GMST changes shown in Table 9.6. The SROCC assessment that past multi-metre sea-level changes have resulted from significant ice sheet changes beyond those presently observed is confirmed (*very high confidence*).

[a]Based on one study (Irvalı et al., 2020) relative to ~year 2000 SST values

[END TABLE 9.6]

Mid-Pliocene Warm Period (MPWP)

During the MPWP, GMST was 2.5-4°C warmer than 1850-1900 (*medium confidence*) and GMSL was between 5 and 25 m higher than today (Table 9.6) (*medium confidence*) (Section 2.3.3.3). The AR5 (Masson-Delmotte et al., 2013) concluded that ice-sheet models consistently produce near-complete deglaciation of the Greenland and West Antarctic Ice Sheets, and multi-meter loss of the East Antarctic Ice Sheet in response to MPWP climate conditions. Studies since the AR5 have yielded a consistent but broader range, due in part to larger ensembles exploring more parameters (DeConto and Pollard, 2016; Yan et al., 2016; DeConto et al., 2021). Partly on the basis of these studies the SROCC proposed a 'plausible' upper bound on GMSL of 25 m (*low confidence*) with evidence suggesting an Antarctic contribution of anywhere between 5.4 – 17.8 m.

The MPWP climate had substantial polar amplification (up to 8 ºC above pre-industrial levels in Arctic Russia, (Fischer et al., 2018); Section 7.4.4.1). Ice sheet model simulations indicate that Northern Hemisphere glaciation was limited to high-elevation regions in eastern and southern Greenland (Figure 9.17) (*medium confidence*)(De Schepper et al., 2014; Yan et al., 2014; Koenig et al., 2015; Dowsett et al., 2016;

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Berends et al., 2019) with Northern Hemisphere glaciation only becoming more widespread from the (cooler) late Pliocene (Bachem et al., 2017; Blake-Mizen et al., 2019; Knutz et al., 2019; Sánchez-Montes et al., 2020). Southern Hemisphere glaciation was characterised by an Antarctic ice sheet reduced in volume from present (Figure 9.18) (Dowsett et al., 2016; Berends et al., 2019; Grant et al., 2019; Miller et al., 2020) (*medium confidence*) with mountain ice fields in the Andes of South America (De Schepper et al., 2014). Ice sheet models are inconsistent in the magnitude of the sea level contribution from Antarctica (DeConto and Pollard, 2016; Yan et al., 2016; Golledge et al., 2017b; Berends et al., 2019; DeConto et al., 2021) but near-field sedimentological reconstructions support precessionally-modulated and eccentricity-paced multi-metre sea level contributions from the Wilkes Subglacial Basin over 3 – 5 kyr (Patterson et al., 2014; Bertram et al., 2018). In summary, under a past warming level of around 2.5 – 4 ºC, ice sheets in both hemispheres were reduced in extent compared to present (*high confidence*). Proxy-based evidence (Section 2.3.3.3) combined with numerical modelling indicates that, on millennial timescales, the GMSL contribution arising from ice sheets was >5 m (*high confidence*) or >10 m (*medium confidence*) (Moucha and Ruetenik, 2017; Berends et al., 2019; Dumitru et al., 2019) (Figures 9.17, 9.18).

Marine Isotope Stage 11 (MIS 11)

The SROCC (Meredith et al., 2019) noted that Greenland may have been ice-free for extensive periods during Pleistocene interglaciations, implying a high sensitivity of the Greenland ice sheet to warming levels close to present day. The AR5 (Church et al., 2013a) assigned *medium confidence* to a MIS 11 GMSL of 6–15 m above present, requiring a loss of much of the Greenland and West Antarctic ice sheets, and a possible contribution from East Antarctica. High-resolution multi-proxy sea surface temperature reconstructions and climate model simulations concur that MIS 11 was an extremely long interglacial that exhibited positive annual (0.5 ± 1.6 ºC, (Irvalı et al., 2020)) and summer (2.1–3.4 ºC, (Robinson et al., 2017)) temperature anomalies (de Wet et al., 2016). GMSL was 6-13 m above present (*medium confidence*, Section 2.3.3.3). The Greenland Ice Sheet lost 4.5–6 m (Reyes et al., 2014)) or ca. 6.1 m (3.9–7 m, 95% confidence) sea-level equivalent by ca. 7 kyr after peak summer warmth (Robinson et al., 2017), with marine-based ice from AIS (Blackburn et al., 2020) contributing 6.4–8.8 m sea-level equivalent at this time (Mas e Braga et al., 2021). Agreement between GMSL and ice-sheet reconstructions gives *high confidence* in identifying a high sensitivity of both ice sheets to the protracted duration of thermal forcing even at low warming levels (Reyes et al., 2014; Robinson et al., 2017; Irvalı et al., 2020; Mas e Braga et al., 2021). Modelled mean mass loss rates for the Greenland Ice Sheet of 0.4 m kyr^{-1} during MIS 11 (Robinson et al., 2017) are indistinguishable from recent mass loss rates averaged over 1992–2018 (Section 9.4.1.1). In summary, geological reconstructions and numerical simulations consistently show that past warming levels of <2 ºC (GMST) are sufficient to trigger multi-metre mass loss from both the Greenland and Antarctic ice sheets if maintained for millennia (*high confidence*), in agreement with the SROCC findings for comparable warming levels during MIS 5e, the Last Interglacial.

Last Interglacial (LIG)

The AR5 found the LIG GMSL was >5 m (*very high confidence*) but <10 m (*high confidence*). Their best estimate of 6 m was based on two studies (Kopp et al., 2009; Dutton and Lambeck, 2012). The SROCC concluded that during the Last Interglacial the Greenland contribution to the GMSL highstand of 6–9 m increased gradually whereas the Antarctic contribution occurred early, from ca. 129 ka. Due to widely varying reconstructions from model studies (Greenland) and the paucity of direct evidence of ice sheet change (Antarctic), the magnitude of sea-level contributions from both ice sheets was assigned *low confidence.*

Since the AR5, information about the LIG, when GMST was about 0.5-1.5°C above 1850-1900 *(medium confidence)* (Section 2.3.1.1), has improved. The LIG had higher summer insolation than present and polar amplified sea surface and surface air temperatures that reached >1–4 ºC and >3–11 ºC in the Arctic respectively (Landais et al., 2016; Capron et al., 2017; Fischer et al., 2018). Mean annual and maximum summer ocean temperatures peaked early (129 –125 ka) in the interglacial period, reaching 1.1 ± 0.3 ºC above the modern global mean (Shackleton et al., 2020) with summer anomalies of 2.5–3.5 ºC in the Southern Ocean (Bianchi and Gersonde, 2002) and spatially variable timing (Chadwick et al., 2020). It is *virtually certain* GMSL was higher than today, *likely* by 5–10 m (*medium confidence*) (Section 2.3.3.3). Global mean thermal expansion peaked at about 0.9 ± 0.3 m early in the LIG (~129 ka), declining to modern

ACCEPTED VERSION SUBJECT TO FINAL EDITING

levels by about 127 ka (Shackleton et al., 2020). With no more than 0.3 ± 0.1 m of GMSL rise from glaciers (Section 9.5.1), at most 1.0 ± 0.3 m of the GMSL rise originated from sources other than the polar ice sheets.

Recent LIG ice sheet simulations agree that peak loss from the Greenland Ice sheet occurred late (125–120 ka) (Goelzer et al., 2016; Tabone et al., 2018; Plach et al., 2019) when Northern Hemisphere insolation was greater than at present (Capron et al., 2017) (*medium confidence*), consistent with inferences from marine sediment records (Hatfield et al., 2016; Irvalı et al., 2020) and far-field GMSL indicators (Rohling et al., 2019). Best estimates of the GMSL contribution from Greenland (Figure 9.17) differ between models: <=1 m (Albrecht et al., 2020; Clark et al., 2020), 1–2 m (Calov et al., 2015; Goelzer et al., 2016; Bradley et al., 2018), up to 3 m (Tabone et al., 2018; Plach et al., 2019), >5 m (Yau et al., 2016). There is *high confidence* that the response time of the Greenland Ice Sheet to LIG warming was multi-millennial and *high confidence* that it contributed to LIG GMSL change, but *low agreement* in the contribution magnitude.

Far-field GMSL records suggest that the Antarctic Ice Sheet contributed to LIG sea level from 129.5–125 ka (Figure 9.18) but direct evidence is sparse. Thinning of part of the West Antarctic Ice Sheet is interpreted from a 130 ka–80 ka hiatus in the Patriot Hills horizontal ice core record (Turney et al., 2020). Marine sediment records suggest a dynamic response of the Wilkes Subglacial Basin (WSB) of the East Antarctic Ice Sheet during this period indicating a response timescale of 1000–2500 yr (Wilson et al., 2018), consistent with modelling studies (Mengel and Levermann, 2014; Golledge et al., 2017b; Sutter et al., 2020). Isotopic changes in the Talos Dome ice core are inconsistent with local surface lowering, limiting retreat to 0.4–0.8 m SLE from this sector (Sutter et al., 2020). Ice sheet models forced with unmodified atmosphere–ocean models (Goelzer et al., 2016; Clark et al., 2020) simulate 3–4.4 m sea-level equivalent mass loss, primarily from the West Antarctic Ice Sheet, with no retreat in WSB (e.g., Figure 9.18). Models forced with proxy-based or ad hoc LIG ocean temperature anomalies (DeConto and Pollard, 2016; Sutter et al., 2016) indicate collapse of West Antarctica under 2–3 ºC ocean forcing yielding 3–7.5 m sea-level contribution, but modest or no retreat in the WSB. Based on *limited evidence* and *limited agreement* between models, there is *low confidence* in both the magnitude and timing of LIG mass loss from the Antarctic Ice Sheet.

In summary, paleo-environmental and modelling studies both indicate that under past warming of the level achieved during the LIG (ca. 0.5–1.5 ºC) it is *likely* that both the Greenland and Antarctic ice sheets responded dynamically over multiple millennia (*high confidence*)

Last Glacial Maximum (LGM)

At the LGM geological proxies and GIA models indicate that GMSL was 125-134 m below present (Section 2.3.3.3; Figures 9.17, 9.18). New studies have not changed the conclusions of the AR5 regarding the size or timing of the LGM and last glacial termination but have further examined the LGM sea-level budget. Based on a synthesis of multiple prior studies, (Simms et al., 2019) estimated central 67% probability contributions to the LGM lowstand of 76 ± 7 m from the North American Laurentide ice sheet, 18 ± 5 m from the Eurasian ice sheet, 10 ± 2 m from Antarctica, 4 ± 1 m from Greenland, 5.5 ± 0.5 m from glaciers, and 2.4 ± 0.3 m due to an increase in ocean density. Of the residual, up to about 1.4 m may be ascribed to groundwater, leaving a shortfall of 16 ± 10 m yet to be allocated among land ice reservoirs or lakes.

Last Deglacial Transition: Meltwater pulse 1A (MWP-1A)

During MWP-1A, GMSL *very likely* (*medium confidence*) rose by 8–15 m (Liu et al., 2016). Consistent with the AR5, the drivers of this rapid rise remain ambiguous. The spatial patterns of relative sea-level change over this interval are inadequately observed to constrain the relative contributions of the North American and Antarctic ice sheets (Liu et al., 2016). Modelling studies of the North American ice sheet permit a 3-6 m (Gregoire et al., 2016) or 6-9 m contribution over the duration of MWP-1A (Tarasov et al., 2012). Sedimentological evidence (Weber et al., 2014; Bart et al., 2018) provides near-field evidence for an Antarctic contribution, consistent with modelling studies (Golledge et al., 2014; Stuhne and Peltier, 2015), but does not constrain the magnitude of the contribution. A recent statistical analysis of Norwegian Sea and Arctic Ocean sediments suggests a 3-7 m contribution from the Eurasian Ice Sheet (Brendryen et al., 2020), a possibility not considered in the AR5 or the meta-analysis of (Liu et al., 2016). In summary, MWP-1A appears to have been driven by a combination of melt in North America (*high confidence*), Eurasia (*low confidence*), and Antarctica (*low confidence*), but the budget is not closed.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Holocene

Around half (~50–60 m) of the GMSL rise since the LGM occurred during the early Holocene at a sustained rate of ~15 m kyr^{-1} from ~11.4–8.2 ka (Lambeck et al., 2014), possibly punctuated by abrupt meltwater pulses (Smith et al., 2011; Carlson and Clark, 2012; Törnqvist and Hijma, 2012; Harrison et al., 2019). An abrupt ~1.1 m sea-level rise at ~8.2 ka was associated with drainage of the pro-glacial lakes Agassiz and Ojibway, attributed to accelerated melt from collapsing Laurentide Ice Sheet ice saddles (Matero et al., 2017). The Laurentide Ice Sheet provided the greatest contribution (27 m) to early Holocene GMSL (Peltier et al., 2015; Roy and Peltier, 2017), the Scandinavian ice sheet contributed ~2 m from the beginning of the Holocene until its demise by ~10.5 ka, (Cuzzone et al., 2016), whilst the Barents Sea ice sheet contributed a small but unknown amount (Patton et al., 2015, 2017; Auriac et al., 2016). The Greenland Ice Sheet contributed ~4 m, consistent with ice thinning rates inferred from the Camp Century ice core (Lecavalier et al., 2017; McFarlin et al., 2018). Recent estimates of Antarctic contributions during the early Holocene vary considerably from ~1.2 m to ~8.5 m (Whitehouse et al., 2012; Ivins et al., 2013; Argus et al., 2014; Briggs et al., 2014; Golledge et al., 2014; Pollard et al., 2016; Roy and Peltier, 2017; Albrecht et al., 2020). In summary, the early Holocene was characterised by steadily rising GMSL as global ice sheets continued to retreat from their LGM extents. This steady rise was punctuated by abrupt pulses during episodes of rapid meltwater discharge.

In the middle Holocene, GMST peaked at 0.2-1.0°C higher than 1850-1900 temperature between 7 and 6 ka (Section 2.3.1.1.2). GMSL rise slowed coincidently with final melting of the Laurentide ice sheet by 6.7 ± 0.4 ka (Ullman et al., 2016), after which only Greenland and Antarctic ice sheets could have contributed significantly. At 6 ka, GMSL was -3.5 to +0.5 m (*medium confidence*) (Section 2.3.3.3). Simulations of the Holocene Thermal Maximum (HTM) give a Greenland ice sheet broadly consistent with geological reconstructions so, despite uncertainties regarding the timing of minimum ice sheet volume and extent, there is *medium confidence* that minima were reached at different times in different areas during the period 8-3 ka BP (Larsen et al., 2015; Young and Briner, 2015; Briner et al., 2016). Geochronological and numerical modelling studies indicate that it is *likely* (*medium confidence*) that the period of smaller-than-present ice extent in all sectors of Greenland persisted for at least 2000 to 3000 years (Larsen et al., 2015; Young and Briner, 2015; Briner et al., 2016; Nielsen et al., 2018). Based on ice sheet modelling and ^{14}C dating (Kingslake et al., 2018) suggested that West Antarctic grounding lines retreated prior to ~10 ka BP, followed by a readvance. Other studies from the same region conclude that retreat was fastest from 9 to 8 ka BP (Spector et al., 2017), or from 7.5 to 4.8 ka BP (Venturelli et al., 2020). Marine geological evidence indicates open marine conditions east of Ross Island by 8.6 ± 0.2 ka BP (McKay et al., 2016). In the western Weddell Sea, (Johnson et al., 2019) reported rapid glacier thinning from 7.5 to 6 ka BP. (Hein et al., 2016) concluded that the fastest thinning further south took place from 6.5 to 3.5 ka BP, potentially contributing 1.4-2 m to GMSL. Geophysical data indicate stabilisation or readvance in this area around 6 ± 2 ka BP (Wearing and Kingslake, 2019). In coastal Dronning Maud Land (East Antarctica) rapid thinning occurred 9 to 5 ka BP (Kawamata et al., 2020), whereas glaciers in the Northern Antarctic Peninsula receded during the period 11 to 8 ka BP and readvanced to their maximal extents by 7 to 4 ka BP (Kaplan et al., 2020). In summary, higher-than-pre-industrial GMST during the mid Holocene coincided with recession of the Greenland Ice Sheet to a smaller-than-present extent (*high confidence*). Multiple lines of evidence give *high confidence* that thinning or retreat in parts of Antarctica during the Holocene took place at different times in different places, but limited data means there is only *low confidence* in whether or not the ice sheet as a whole was smaller than present during the mid Holocene.

In summary, both proxies and model simulations indicate that GMSL changes during the early to mid Holocene were the result of episodic pulses, due to drainage of meltwater lakes, superimposed on a trend of steady rise due to continued ice sheet retreat (*high confidence*).

The combination of tide gauge observations and geological reconstructions indicates that a sustained increase of GMSL began between 1820 and 1860 and led to a 20th century GMSL rise that was *very likely* (*high confidence*) faster than in any preceding century in the last 3000 yr (Section 2.3.3.3). At a regional level, tide gauge and geological data from the North Atlantic and Australasia show inflections in relative sea-level trends between 1895-1935, with an increase of 0.8 to 2.5 mm yr^{-1} across the inflection (Gehrels and Woodworth, 2013). A statistical meta-analysis of globally distributed geological and tide gauge data (Kopp

ACCEPTED VERSION SUBJECT TO FINAL EDITING

et al., 2016) found that, in all twenty examined regions with geological records stretching back at least 2000 years, the rate of RSL rise in the 20th century was greater than the local average over 0-1700 CE. In four of the twenty regions, all in the North Atlantic (Connecticut, New Jersey, North Carolina, and Iceland), the 19th century rate was also greater than the 0-1700 CE average (90% confidence interval). In summary, rates of RSL rise exceeding the pre-industrial background rate of rise are apparent in parts of the North Atlantic in the nineteenth century (*medium confidence*) and in most of the world in the twentieth century (*high confidence*).

9.6.3 Future sea-level changes

This section first assesses sea-level projections since the AR5 (Church et al., 2013a) (and including the SROCC (Oppenheimer et al., 2019)) based on Representative Concentration Pathways (Section 9.6.3.1). Process-level assessments in sections 9.2.4, 9.4.1.3, 9.4.1.4, 9.4.2.5, 9.4.2.6 and 9.5.1.3 are synthesised (Section 9.6.3.2) to produce new global-mean and regional sea-level projections based on the Shared Socioeconomic Pathways up to 2150 (Section 9.6.3.3) and on global warming levels up to 2100 (Section 9.6.3.4). Long-term global mean sea-level projections, both at 2300 and on multimillennial timescales, are also assessed (Section 9.6.3.5).

In sections 9.6.3.3 and 9.6.3.4, *likely* ranges of the new global-mean sea-level projections are presented, incorporating only processes in whose projections there is at least *medium confidence*, consistent with headline projections in the AR5 and the SROCC. As emphasized by the SROCC, there is a substantial likelihood that sea level rise will be outside the *likely* range. As described in Box 1.1, since the definition of '*likely'* refers to at least 66% probability, there may be as much as a 34% probability that the processes in which there is at least *medium confidence* will generate outcomes outside the *likely* range. Furthermore, additional processes in which there is *low confidence* (Section 9.4.2.4; Box 9.4) may also contribute to sea-level change. The presentation of *likely* sea-level change (Tables 9.8-9.9 and in Figures 9.27, 9.29) is therefore accompanied by a *low confidence* range intended to reflect potential contributions from additional processes under high-emissions scenarios. The *low confidence* range incorporates ice-sheet projections based on both structured expert judgement (i.e., a formal, calibrated method of combining quantified expert assessments that incorporate all potential processes) and projections from an Antarctic ice sheet model that includes the Marine Ice Cliff Instability (a specific uncertain process not generally included in ice sheet models; Section 9.4.2.4).

9.6.3.1 Global mean sea level projections based on the Representative Concentration Pathways

The AR5 (Church et al., 2013a) generated global mean sea level (GMSL) projections for the Representative Concentration Pathways (RCPs) by combining information from CMIP5 climate models with glacier and ice-sheet surface mass balance models and assessments of projected ice-sheet dynamic and land-water storage contributions (Section 9.6.3.2). The SROCC (Oppenheimer et al., 2019) updated the AR5 projections based upon a revised assessment of the Antarctic ice sheet contribution to GMSL rise. The AR5 and the SROCC employ a baseline period of 1986 to 2005, which is updated in this report to a baseline period of 1995 to 2014 (Section 1.4.1). Between these two periods, GMSL rose by 3 cm and this correction is applied to projections from previous reports to allow comparison (Table 9.8). Accounting for this shift, the conclusion of the SROCC is that, with *medium confidence*, GMSL will rise between 0.40 m (0.26–0.56 m, *likely* range) (RCP 2.6) and 0.81 m (0.58–1.07 m, *likely* range) (RCP 8.5) by 2100 relative to 1995-2014. The AR5 and the SROCC projections of GMSL for the 2007-2018 period have been shown to be consistent with observed trends in GMSL and regional weighted mean tide gauges (Wang et al., 2021a).

Since the AR5, , a number of projections of GMSL rise have been published based on the RCPs (Slangen et al., 2014a; Kopp et al., 2014, 2017; Grinsted et al., 2015; Jackson et al., 2016; Mengel et al., 2016; Bakker et al., 2017; Bittermann et al., 2017; Nauels et al., 2017; Wong et al., 2017; Le Bars et al., 2017; Nicholls et al., 2018; Goodwin et al., 2018; Le Cozannet et al., 2019; Palmer et al., 2020)(see (Garner et al., 2018) for a database; Tables 9.SM.5, 9.SM.6). Some studies also produced associated global sets of regional projections

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Kopp et al., 2014, 2017; Slangen et al., 2014a; Le Cozannet et al., 2019; Palmer et al., 2020). Since the SROCC, (Le Cozannet et al., 2019) focussed on the low end of the probability distribution of GMSL rise, (Palmer et al., 2020) extended projections beyond 2100 using a climate model emulator (Cross-Chapter Box 7.1) and (Horton et al., 2020) conducted a survey of 106 sea-level experts, providing additional context for interpreting sea-level rise projections for 2100 and 2300.

As noted by the SROCC, the largest differences between projections of GMSL in 2100 are due to the ice sheet projection method, which generally fall into one of three categories: (1) projections from ice sheet models that represent processes in which there is at least *medium confidence* (Sections 9.4.1.2, 9.4.2.2), (2) projections from an Antarctic ice-sheet model that incorporates the Marine Ice Cliff Instability (MICI) (Section 9.4.2.4) (DeConto and Pollard, 2016), or (3) projections based on structured expert judgement (SEJ) (Sections 9.4.1.3; 9.4.1.4; 9.4.2.5; 9.4.2.6) (Bamber and Aspinall, 2013; Bamber et al., 2019). *Low confidence* is ascribed to projections incorporating MICI because there is *low confidence* in the current ability to quantify MICI (Section 9.4.2.4). *Low confidence* is also ascribed to projections based on SEJ, because individual experts participating in the SEJ study may have incorporated processes in whose quantification there is *low confidence*, and the experts' reasoning has not been examined in detail. In general, the range of GMSL projections based upon ice-sheet models not incorporating MICI overlaps with but is lower than projections incorporating MICI or employing SEJ (Figure 9.25).

There is *high agreement* across published GMSL projections for 2050 and there is little sensitivity to emissions scenario (Figure 9.25, left panel). Up to 2050, projections are broadly consistent with extrapolation of the observed acceleration of GMSL rise (Sections 2.3.3.3, 9.6.1.1, 9.6.1.2). Considering only projections incorporating ice-sheet processes in whose quantification there is at least *medium confidence*, the GMSL projections for 2050, across all emissions scenarios, fall between 0.1 and 0.4 m (5^{th}—95^{th} percentile range). Projections incorporating MICI or SEJ do not extend this range under RCP 2.6 or RCP 4.5 and extend the upper part of the range to 0.6 m under RCP 8.5. On the basis of these studies, we therefore have *high confidence* that GMSL in 2050 will be between 0.1 and 0.4 m higher than in 1995 to 2014 under low and moderate emissions scenarios and between 0.1 and 0.6 m under high emissions scenarios.

Conversely, there is *low agreement* across published GMSL projections for 2100, particularly for higher emissions scenarios, as well as a higher degree of sensitivity to the choice of emissions scenario (Figure 9.25, right panel). Considering only projections representing processes in whose quantification there is at least *medium confidence*, the GMSL projections for 2100 fall between 0.2 and 1.0 m (5^{th}—95^{th} percentile range) under RCP 2.6 and RCP 4.5, and between 0.3 and 1.6 m under RCP 8.5. Considering also projections incorporating MICI or SEJ (*low confidence*), the projections for 2100 fall between 0.2 and 1.0 m (5^{th}—95^{th} percentile range) under RCP 2.6, 0.2 and 1.6 m under RCP 4.5, and 0.4 and 2.4 m under RCP 8.5. In summary, RCP-based projections published since the AR5 show *high agreement* for 2050, but exhibit broad ranges and *low agreement* for 2100, particularly under RCP 8.5.

[START FIGURE 9.25 HERE]

Figure 9.25: Literature global mean sea level (GMSL) projections (m) for 2050 (left) and 2100 (right) since 1995-2014, for RCP 8.5/SSP5-8.5 (top set), RCP 4.5/SSP2-4.5 (middle set), and RCP 2.6/ SSP1-2.6 (bottom set). Projections are standardised to account for minor differences in time periods. Thick bars span from the 17^{th}-83^{rd} percentile projections, and thin bars span the 5^{th}-95^{th} percentile projections. The different assessments of ice sheet contributions are indicated by 'MED' (ice sheet projections including only processes in whose quantification there is *medium confidence*), 'MICI' (ice sheet projections which incorporate Marine Ice Cliff Instability), and 'SEJ' (structured expert judgement (SEJ) to assess the central range of the ice-sheet projection distributions). 'Survey' indicates the results of a 2020 survey of sea-level experts on GMSL rise from all sources (Horton et al., 2020). Projection categories incorporating processes in which there is *low confidence* ('MICI' and 'SEJ') are lightly shaded. Dispersion among the different projections represents *deep uncertainty*, which arises as a result of *low agreement* regarding appropriate conceptual models describing ice sheet behaviour and *low agreement* regarding probability distributions used to represent key uncertainties. Individual studies are shown in Tables 9.SM.5, 9.SM.6.

Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.25 HERE]

9.6.3.2 Drivers of projected sea-level change

This section describes the choices made for the contributions to the updated global mean and regional sea-level projections (Section 9.6.3.3) based on assessments in this report and compares the updated projections to the AR5 (Church et al., 2013a) and the SROCC (Oppenheimer et al., 2019) (Tables 9.7, 9.8). Since there is no single model that can directly compute all of the contributions to sea-level change (Box 9.1), the contributions to sea level are computed separately and then combined (Tables 9.8, 9.9). For consistency with global surface air temperature (GSAT) projections (Section 4.3.1.1) and assessment of equilibrium climate sensitivity (ECS) and transient climate response (TCR) (Section 7.5), temperature-dependent projections (thermal expansion, ice sheets, glaciers) are forced by GSAT projections from a two-layer energy budget emulator (Smith et al., 2018) that is calibrated to be consistent with the assessment of ECS and TCR (Box 7.1, Supplementary Material 7.SM.2). Throughout, *likely* ranges are assessed based upon the combination of uncertainty in the GSAT distribution and uncertainty in the relationships between GSAT and changes to individual components. In general, 17th-83rd percentile results, incorporating both GSAT and sea-level process uncertainty, are interpreted as *likely* ranges. This is distinct from the approach used by the AR5, which interpreted the 5th-95th percentile range of CMIP5 projections and therefore of GMSL projections driven by them as *likely* ranges. The shift in interpretation here is consistent with the use of the emulator for GSAT (Box 4.1, Cross-Chapter Box 7.1). *Very likely* ranges are not assessed because of the potential for processes in whose projections there is currently *low confidence* to substantially augment total projected GMSL change.

Glaciers (including peripheral glaciers) (Section 9.5.1.3)	Power law function of integrated GMST fit to glacier models	Up to 2100: Emulated GlacierMIP (Marzeion et al., 2020; Edwards et al., 2021) simulations (Box 9.3) Beyond 2100: AR5 parametric model re-fit to GlacierMIP (Marzeion et al., 2020) (Supplementary Material 9.SM.4.5)
Land water storage (Section 9.6.3.2)	Groundwater depletion: combination of (1) continuation of early 21st century trends and (2) land-surface hydrology models (Wada et al., 2012) Water impoundment: combination of (1) continuation of historical rate and (2) assumption of no net impoundment after 2010	Groundwater depletion: Population/groundwater depletion relationship calibrated based on (Konikow, 2011; Wada et al., 2012, 2016) Water impoundment: Population/dam impoundment relationship calibrated based on (Chao et al., 2008), adjusted for new construction following (Hawley et al., 2020) for 2020 to 2040
Ocean dynamic sea level (Section 9.2.4.2)	CMIP5 ensemble *zos* field after polynomial drift removal	Distribution derived from CMIP6 ensemble *zos* field after linear drift removal (Supplementary Material 9.SM.4.2, 9.SM.4.3)
Gravitational, rotational, and deformational effects (Section 9.6.3.2)	Sea-level equation solver (Slangen et al., 2014a) driven by projections of ice sheet, glacier, and land water storage changes	

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Glacial isostatic adjustment and other drivers of vertical land motion (Section 9.6.3.2)	GIA model, with ice history from mean of ANU and ICE-5G	Spatiotemporal statistical model of tide-gauge data (updated from (Kopp et al., 2014)) (Supplementary Material 9.SM.4.6)

[a] Ice sheet models include some of the larger islands in the Antarctic periphery, so there is some overlap in the projected glacier contribution and the projected Antarctic contribution, but the effect of this is estimated to be of order 0.5-1 cm or less (Edwards et al., 2021).

[END TABLE 9.7 HERE]

Global Mean Thermosteric Sea-Level Rise

In the AR5 and the SROCC, global mean thermosteric sea-level rise was derived from the 21 members of the CMIP5 ensemble that provided the required variables (Section 9.2.4.1). The AR5 and the SROCC removed drift estimated based on a pointwise polynomial fit to pre-industrial control simulations. They extended projections to scenarios not provided by the models by calculating the heat content of the climate system from global mean surface temperature and net radiative flux, and converting this to global mean thermosteric sea-level rise using each model's diagnosed expansion efficiency coefficient. The AR5 and the SROCC derived the associated uncertainties by assuming a normal distribution, with the 5th-95th percentile CMIP5 ensemble interpreted as the *likely* range. In this report, global mean thermosteric sea-level rise is derived from a two-layer energy budget emulator consistent with the assessment of ECS and TCR (Section 9.2.4.1; Supplementary Material 9.SM.4.2, 9.SM.4.3). Despite the change in methodology, this leads to a *likely* global mean thermosteric contribution (17th-83rd percentile) between 1995 to 2014 and 2100 that represents a minimal change from the AR5 and the SROCC (Table 9.8).

Greenland ice sheet

The AR5 and the SROCC projected the Greenland surface-mass balance using a cubic polynomial fit to a regional climate model as a function of global mean surface temperature (with a log-normal scaling factor reflecting uncertainty in surface-mass balance models, and another scaling factor reflecting the positive feedback of ice-sheet elevation changes on mass loss), and the dynamic contribution was estimated based on a multi-model assessment interpolated as a quadratic function of time.

For processes in whose projections we have at least *medium confidence*, the updated projections use emulated ISMIP6 projections of the Greenland ice sheet (Section 9.4.1.3; Box 9.3; Tables 9.2, 9.7; Figure 9.17). Since the ISMIP6 emulator does not account for temporal correlation, a parametric fit to the ISMIP6 results is employed to calculate rates of change (Supplementary Material 9.SM.4.4). For projections beyond 2100 (when the ISMIP6 simulations end), the polynomial fit is extrapolated based on two alternate approaches: (1) an assumption of constant rates of mass change after 2100, and (2) for SSP1-2.6 and SSP5-8.5, a quadratic function of time extending to 2300 based on the multimodel assessment of contributions under RCP 2.6 and RCP 8.5 at 2300 (Section 9.4.1.4). Differences between the two approaches are small up to 2150, and since the latter approach is not available for all scenarios, only the former (constant rates) is used for time-series projections up to 2150. Both approaches are used for examining uncertainty in the timing of different levels of GMSL rise and to inform projections for the year 2300 (Section 9.4.1.4). For 2100, the ISMIP6 emulator yields the *likely* contribution from the Greenland ice sheet shown in Table 9.2 and Figure 9.17, representing a slight narrowing from the AR5 projections.

Antarctic ice sheet

For the Antarctic ice sheet, the AR5 applied a temperature-based scaling approach for surface mass balance and a quadratic function of time, calibrated to a multimodel assessment, for dynamic contributions. The

ACCEPTED VERSION SUBJECT TO FINAL EDITING

SROCC used a new assessment based on the results of five process-based studies (Section 9.4.2.5). For processes in whose projections we have at least *medium confidence*, the *likely range* projections for the Antarctic ice sheet are based upon 1) the emulated ISMIP6 ensemble and 2) the LARMIP-2 ensemble, augmented with the AR5 parametric Antarctic surface mass balance model. GMSL projections are produced with both distributions and combined in a 'p-box' (Kriegler and Held, 2005; Le Cozannet et al., 2017), which represents the upper and lower bounds of the distribution (Section 9.4.2.5, Box 9.3, Table 9.3). A *likely* range is then identified, spanning the lower of the two 17th percentile projections and the higher of the two 83rd percentile projections[5], with the median taken as the mean of the medians of the two projections. Since the ISMIP6 emulator does not account for temporal correlation, the AR5 parametric AIS model is substituted for the emulator in the p-box for rates of change. As the AR5 projections are modestly lower than those from the ISMIP6 emulator, this substitution modestly broadens the *likely* range at the low end for projections of rate and changes beyond 2100. For projections beyond 2100 (when the ISMIP6 and LARMIP-2 simulations end), the AIS simulations are extrapolated using the same two approaches as the GrIS projections (Section 9.2.4.6). The *likely* ranges to 2100 are consistent with the SROCC (Table 9.8).

Low confidence ice sheet projections

To test the possible effect of additional ice-sheet processes for which there is *low confidence* (Sections 9.4.1.3, 9.4.1.4, 9.4.2.5, 9.4.2.6, 9.6.3.1; Box 9.4), two additional approaches are considered. For both the Greenland and Antarctic ice sheets, we produce sensitivity cases employing the SEJ projections of (Bamber et al., 2019), mapping 2°C and 5°C stabilization scenarios to SSP1-2.6 and SSP5-8.5, respectively. For the Antarctic ice sheet, we produce an additional sensitivity case using projections, which incorporate the Marine Ice Cliff Instability (DeConto et al., 2021), mapping projections for RCP 2.6 and RCP 8.5 to SSP1-2.6 and SSP5-8.5. For the Greenland ice sheet, the SEJ projections indicate the potential for outcomes outside the corresponding *likely* ranges (Table 9.8). For the Antarctic ice sheet, there is no evidence from these studies to suggest an important role under lower emissions scenarios for processes in whose projections we have *low confidence*. By contrast, for SSP5-8.5, the SEJ and MICI projections exhibit 17th-83rd percentile ranges of 0.02-0.56 m and 0.19-0.53 m by 2100, consistent with one another but considerably broader than the *likely* contribution for *medium confidence* processes of 0.03 to 0.34 m. This lower level of agreement for higher emissions scenarios reflects the *deep uncertainty* in the AIS contribution to GMSL change under higher emissions scenarios (Box 9.4). This *deep uncertainty* grows after 2100: by 2150, under SSP 5-8.5, *medium confidence* processes *likely* lead to a -0.1 to 0.7 m AIS contribution, while SEJ and MICI-based projections indicate 0.0-1.1 m and 1.4-3.7 m, respectively.

Glaciers

In the AR5 and the SROCC, global glacier mass changes were derived from a power law of integrated global-mean surface temperature change fit to results from four different glacier models. The updated projections use emulated GlacierMIP projections (Section 9.5.1.3, Box 9.3). Since the GlacierMIP emulator does not account for temporal correlation and terminates, along with the GlacierMIP simulations, in 2100, we employ a parametric fit to the GlacierMIP simulations, with a functional form similar to that employed by the AR5, to calculate rates of change and extrapolate changes beyond 2100 (up to a maximum potential contribution of 0.32 m) (see Supplementary Material 9.SM.4.5). This approach leads to a median glacier contribution that is a minimal change (Table 9.8) from the AR5 and the SROCC and a modest narrowing of *likely* ranges (Section 9.5.1.3). For RCP 2.6, the AR5 projected 0.10 (0.04-0.16, *likely* range) m, compared to 0.09 (0.07-0.11) m projected here for SSP1-2.6. For RCP 8.5, the AR5 projected a *likely* contribution of 0.17 (0.09-0.25) m, compared to 0.18 (0.15-0.21) m projected here.

Land water storage

In the AR5 and the SROCC, the groundwater depletion contribution to GMSL rise was based on combining results from two approaches, one assuming a continuation of early 21st century trends (Konikow, 2011) and the other using land-surface hydrology models (Wada et al., 2012). Together, these yielded a range of about 0.02-0.09 m of GMSL rise by 2080-2099. The rate of water impoundment in reservoirs was likewise based

[5] Note that the use of this approach implies that the *likely* ranges are *likely* in the use of the term to mean 66–100% probable; this is distinct from the usage in the SROCC, where *likely* range was defined to have a precise 66% probability.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

on two approaches, one assuming the continuation of the average rate over 1971-2010 (and thus -0.01 to -0.03 m by 2080-2099) (Chao et al., 2008), and the other assuming no net impoundment after 2010 (Lettenmaier and Milly, 2009). Together, these yield a GMSL contribution from groundwater impoundment of -0.03 to 0 m. Combining groundwater depletion and water impoundment led the AR5 and the SROCC to infer a projected range of -0.01 to +0.11 m by 2100.

In the updated projections, a statistical relationship is applied linking historical and future SSP global population to dam impoundment and groundwater extraction (Rahmstorf et al., 2012; Kopp et al., 2014). The population/groundwater depletion relationship is calibrated based on the same studies used in the AR5 (Konikow, 2011; Wada et al., 2012), reduced by ~20% to account for water retained on land (Wada et al., 2016). The population/dam impoundment relationship is calibrated based upon (Chao et al., 2008). However, while historically dam impoundment has been declining with population, recent literature shows that planned dam construction considerably exceeds the historical trend (Zarfl et al., 2015; Hawley et al., 2020). Over 2020-2040, the impoundment contribution to GMSL rise based upon past trends would be about -0.1 mm yr^{-1}, compared to about -0.5 mm yr^{-1}if all currently planned dams are built (Hawley et al., 2020) and the statistical projection is therefore augmented by an additional -0.4 to 0.0 mm yr^{-1}over 2020-2040 to account for the possible effects of planned dam construction. As in the AR5 and the SROCC, climatically driven changes to LWS have not been included in published sea-level projections, as they are not well quantified (e.g., (Jensen et al., 2019)) or are considered negligible (e.g., permafrost, Section 9.5.2). This approach yields a *likely* global-mean land water storage contribution (Figure 9.27, Table 9.8) that is slightly lower and narrower than the AR5 and the SROCC *likely* ranges. Since the projections are explicitly population driven, these projections also exhibit a weak scenario dependence, with a ~0.01 m higher contribution under SSP3 than under other scenarios.

[START TABLE 9.8 HERE]

Table 9.8: Global mean sea-level projections between 1995-2014 and 2100 for total change and individual contributions, median values, (*likely*) ranges of the process-based model ensemble, for RCP 2.6 (from the AR5 (Church et al., 2013b) and the SROCC (Oppenheimer et al., 2019)) and SSP1-2.6 (this report), and for RCP 8.5 (from the AR5 (Church et al., 2013b) and the SROCC (Oppenheimer et al., 2019)) and SSP5-8.5 (this report). Values for the AR5 (Church et al., 2013b) and the SROCC (Oppenheimer et al., 2019) are adjusted from the 1986-2005 baseline used in past reports. Only the Antarctic contribution changed between the AR5 (Church et al., 2013b) and the SROCC (Oppenheimer et al., 2019). Unshaded cells represent processes in which there is *medium confidence*; shading indicates the inclusion of processes in which there is *low confidence*. For the MICI and SEJ-based projections, parenthetical numbers represent the 17-83rd percentile of the associated probability distributions, not assessed *likely* ranges.

Ocean dynamic sea level

In the AR5 and the SROCC, the ocean dynamic sea-level contribution to relative sea-level (RSL) projections was derived from the CMIP5 ensemble, after removing drift estimated based on pre-industrial control simulations. This report uses updated simulations from the CMIP6 ensemble (Section 9.2.4.2; Supplementary Material 9.SM.4.2) to project the ocean dynamic sea-level contribution to relative sea-level change (Figure 9.26; Section 9.2.4.2). To produce ocean dynamic sea-level projections consistent with the global mean thermosteric projections from the two-layer energy budget emulator, we follow the approach of (Kopp et al., 2014), employing a correlation between global-mean thermosteric sea-level change and ocean dynamic sea level derived from the CMIP6 ensemble (Supplementary Material 9.SM.4.3). Since CMIP6 models are of fairly coarse (typically ~100km) resolution, and even the models participating in HighResMIP (near 10km resolution) do not capture all the phenomena that contribute to coastal ocean dynamic sea-level change, there is *low confidence* in the details of ocean dynamic sea-level change along the coast (Section 9.2.3.6) and in semi-enclosed basins, like the Mediterranean, where coarse models can misrepresent key dynamic processes. Regional high-resolution models can improve projections of coastal ocean dynamic sea-level change (Section 12.4) (Hermans et al., 2020), but have not been implemented at a global scale.

Gravitational, rotational, and deformational (GRD) effects

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GRD effects (Box 9.1) lead to distinct variations in the RSL change pattern, which are similar across a range of benchmarked GRD solvers (Martinec et al., 2018; Palmer et al., 2020). There is *high confidence* in the understanding of GRD processes. RSL rise associated with GRD is *very likely* to be largest in the Pacific, due to the combined effects of projected GrIS, AIS and glacier mass loss (*high confidence*) (e.g., Kopp et al., 2014; Slangen et al., 2014a; Larour et al., 2017; Mitrovica et al., 2018). The GRD effect associated with mass loss from an ice sheet is sensitive to the spatial distribution of that mass loss. For example, the GRD contribution to RSL rise in Australia will be larger for Antarctic mass loss sourced fromthe Antarctic Peninsula than for Antarctic mass loss sourced fromThwaites Glacier. In parts of northeastern North America and northwestern Europe, GRD effects associated with mass loss from southern Greenland will lead to a RSL fall, whereas mass loss from northern Greenland will lead to a RSL rise (*high confidence*) (Larour et al., 2017; Mitrovica et al., 2018) (Figure 9.26). The AR5 and the SROCC computed RSL patterns using a gravitationally self-consistent GRD solver given the amounts, locations and timing of the projected barystatic sea-level changes driven by glaciers, ice sheets and LWS (Church et al., 2013a). A similar GRD solver is used in the updated projections (following (Slangen et al., 2014a)). The Earth model used is based on PREM (Dziewonski and Anderson, 1981), and is elastic, compressible and radially stratified.

Glacial isostatic adjustment and other drivers of vertical land motion

Glacial Isostatic Adjustment (GIA; Box 9.1) leads to vertical land motion (VLM; Box 9.1) and changes in sea-surface height, both of which contribute to RSL change. GIA uncertainty is caused by uncertainty in the rheological structure of the solid Earth, which drives the longer-term viscous Earth deformation, as well as in the modelled global ice history (e.g., Whitehouse, 2018). In the AR5 and the SROCC, GIA contributions to relative sea-level change were calculated using a sea-level equation solver with an ice-sheet history taken as the mean of the ICE5G (Peltier et al., 2015) and ANU (Lambeck et al., 2014) ice sheet models. Since the AR5, new global models are emerging that more rigorously treat ice and Earth structure uncertainty (Caron et al., 2018). However, there is also a growing recognition that lateral variations in Earth structure limit the utilityof global models that treat the solid Earth as though it were laterally uniform (Love et al., 2016; Huang et al., 2019; Li et al., 2020c).

As noted by the SROCC, VLM from sources other than GIA – including tectonics and mantle dynamic topography, volcanism, compaction, and anthropogenic subsidence – can be locally important, producing VLM rates comparable to or greater than rates of GMSL change. Complete global projections of these processes are not available because of the small spatial scales, the sensitivity of subsidence to local human activities, and the stochasticity of tectonics (Wöppelmann and Marcos, 2016; Oppenheimer et al., 2019). Integrated RSL projections to date have therefore either included only the component of VLM associated with GIA, as in the AR5 and SROCC, or used a constant long-term background rate of change (including both GIA and other long-term drivers of VLM) estimated from historical tide gauge trends (e.g., (Kopp et al., 2014)). The updated projections use the second approach and extrapolate the field of long-term background rates of RSL change, including long-term VLM derived from tide gauges, to global coverage using a spatiotemporal statistical approach (Kopp et al., 2014) (Supplementary Material 9.SM.4.6). The combined GIA and long-term VLM is assumed to be constant over the projected period and scenario independent. In areas (e.g., the western Gulf of Mexico) where rapid subsidence occurs in a cluster of tide-gauges, the associated rates are interpolated between the tide gauges. In areas where the available tide-gauges exhibit large, tectonically driven VLM that changes considerably in rate over short distances (e.g., Alaska and the Bering Strait) a sizable uncertainty propagates into the RSL projections (Figure 9.26). Rates of RSL rise are likely to be underestimated due to subsidence in shallow strata that are not recorded by tide gauges (Keogh and Törnqvist, 2019) and in some locations may therefore be minimum values, especially if anomalously high subsidence rates associated with fluid extraction (e.g., (Minderhoud et al., 2017)) are also considered. There is therefore, depending on location, *low* to *medium confidence* in the GIA and VLM projections employed in this report. In many regions, higher fidelity projections would require more detailed regional analysis.

Figure 9.26: Median global mean and regional relative sea-level projections (m) by contribution for the SSP1-2.6 and SSP5-8.5 scenarios. (upper time series) Global mean contributions to sea-level change as a function of time, relative to 1995-2014. (lower maps) Regional projections of the sea-level contributions in 2100 relative to 1995-2014 for SSP5-8.5 and SSP1-2.6. Vertical land motion is common to both SSPs. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.26 HERE]

9.6.3.3 Sea-level projections to 2150 based on SSP scenarios

Up to 2050, consistent with the AR5 and the SROCC, GMSL projections exhibit little scenario dependence (Figure 9.27, Table 9.9) (*high confidence*), with *likely* (*medium confidence*) sea-level rise between the baseline period (1995 to 2014) and 2050 of 0.19 (0.16-0.25) m under SSP1-2.6 and 0.23 (0.20-0.30) m under SSP5-8.5. These projections fall centrally within the range of published projections for RCP 2.6 and RCP 8.5 (Section 9.6.3.1).

Beyond 2050, the scenarios increasingly diverge. Between the baseline period (1995 to 2014) and 2100, processes in whose projection there is *medium confidence* drive *likely* GMSL rise of 0.44 m (0.33-0.61) m and 0.77 (0.63-1.02) m under SSP1-2.6 and SSP5-8.5, respectively (Tables 9.8, 9.9). While derived using substantially updated methods, these projections are broadly consistent with the SROCC, which over this period projected *likely* GMSL rise of 0.41 (0.26-0.56) m and 0.81 (0.58-1.07) m under RCP 2.6 and RCP 8.5, respectively. They are modestly higher than those of the AR5, which projected *likely* GMSL rise of 0.41 (0.25-0.58) m under RCP 2.6 and 0.71 (0.49-0.95) m under RCP 8.5 (Figure 9.25, Table 9.8). They are also broadly consistent with projections produced by driving the AR5 methods with CMIP6 temperature and thermal expansion projections, which leads to 0.44 (0.27-0.61) m under SSP1-2.6 and 0.73 (0.49-1.02) m under SSP5-8.5 (Hermans et al., 2021). The SSP1-2.6 and SSP5-8.5 projections are consistent with the ranges of published projections for RCP 2.6 and RCP 8.5 that do not incorporate MICI or SEJ (Section 9.6.3.1).

The *likely* GMSL projections for SSP3-7.0 and SSP5-8.5 are consistent with a continuation of the GMSL satellite-observed rate (*very likely* 3.25 [2.88-3.61] mm yr^{-1}) and acceleration (*very likely* 0.094 [0.082-0.115] mm yr^{-2}) of GMSL rise over 1993-2018 (Table 9.5 and Section 2.3.3.3), which would imply a *likely* GMSL rise of 0.24 m (0.23-0.25 m) by 2050 and 0.73 m (0.69-0.77 m) by 2100. This extrapolation would also imply a *likely* rate of GMSL rise of 7.5 (7.4-7.6) mm yr^{-1}over 2040-2060 and 11.2 (10.6-11.8) mm yr^{-1}over 2080-2100. Over the satellite period, the observed acceleration has been driven primarily by ice-sheet contributions (Section 9.6.1.2; Table 9.5); in the median projections for SSP3-7.0 and SSP5-8.5, these accelerations are projected to continue at a slightly lower level, while the GMSL acceleration is augmented by an acceleration of thermal expansion and glacier loss associated with rising global temperature. Overall, these extrapolations imply that, under SSP1-1.9, SSP1-2.6, and SSP2-4.5, the GMSL acceleration is projected to decrease from its current level.

[START TABLE 9.9 HERE]

Table 9.9: Global mean sea-level projections for 5 SSP scenarios, relative to a baseline of 1995-2014, in meters. Individual contributions are shown for the year 2100. Median values (*likely* ranges) are shown. Average rates for total sea-level change are shown in mm yr^{-1}. Unshaded cells represent processes in whose projections there is *medium confidence*. Shaded cells incorporate a representation of processes in which there is *low confidence*; in particular, the SSP5-8.5 *low confidence* column shows the 17th-83rd percentile range from a p-box including SEJ- and MICI-based projections rather than an assessed *likely* range. Methods are described in 9.6.3.2.

[END TABLE 9.9 HERE]

While ice-sheet processes in whose projection there is *low confidence* have little influence up to 2100 on projections under SSP1-1.9 and SSP1-2.6 (Table 9.9), this is not the case under higher emissions scenarios, where they could lead to GMSL rise well above the *likely* range. In particular, under SSP5-8.5, *low-confidence* processes could lead to a total GMSL rise of 0.6-1.6 m over this time period (17^{th}-83^{rd} percentile range of p-box including SEJ- and MICI-based projections), with 5^{th}-95^{th} percentile projections extending to 0.5-2.3 m (*low confidence*). The assessed *low confidence* range is slightly narrower than but broadly consistent with the full 0.4-2.4 m range of published 5^{th}-95^{th} percentile projections for RCP 8.5 since the AR5 (Section 9.6.3.1), including those based on SEJ or incorporating MICI, and highlights the *deep uncertainty* in GMSL rise under the highest emissions scenarios (Box 9.4). The assessment of the potential contribution of processes in which there is *low confidence* to GMSL rise by 2100 is broadly consistent with the assessment of the AR5 (Church et al., 2013a) , which concluded that collapse of marine-based sectors of the Antarctic ice sheet could cause several tenths of a meter of global mean sea-level rise above the *likely* range.

While prior assessment reports, starting with the First Assessment Report (Warrick et al., 1990), have focused on projecting GMSL up to the year 2100, time has progressed, and the year 2100 is now within the timeframe of some long-term infrastructure decisions. For this reason, projections up to the year 2150 are also highlighted (Table 9.9). Over this time period, assuming no acceleration in ice-sheet mass fluxes after 2100, processes in which there is *medium confidence* lead to GMSL rise of 0.5-1.0 m under SSP1-2.6 and 1.0-1.9 m under SSP5-8.5. Processes in which there is *low confidence* could drive GMSL rise under SSP5-8.5 to 1.0-4.8 m (17^{th}-83^{rd} percentile) or even 0.9-5.4 m (5^{th}-95^{th} percentile).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[START FIGURE 9.27 HERE]

Figure 9.27: Projected global mean sea level rise under different SSP scenarios. *Likely* global mean sea-level change for SSP scenarios resulting from processes in whose projection there is *medium confidence*. Projections and *likely* ranges at 2150 are shown on right. Lightly shaded ranges and thinner lightly shaded ranges on the right show the 17th-83rd and 5th-95th percentile ranges for projections including *low confidence* processes for SSP1-2.6 and SSP5-8.5 only, derived from a p-box including Structured Expert Judgement and Marine Ice Cliff Instability projections. Black lines show historical GMSL change, and thick solid and dash-dotted black lines show the mean and *likely* range extrapolating the 1993-2018 satellite altimeter trend and acceleration. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.27 HERE]

Median projected relative sea-level changes are shown in Figure 9.28, with driving factors highlighted in Figure 9.26. Over the 21st century, the majority of coastal locations have a median projected regional sea-level rise within +/- 20% of the median projected GMSL change (*medium confidence*). Consistent with the AR5, loss of land-ice mass will be an important contributor to spatial patterns in relative sea-level change *(high confidence*), with ocean dynamic sea-level being particularly important as a dipolar contributor in the Northwest Atlantic, a positive contributor in the Arctic Ocean, and a negative contributor in the Southern Ocean south of the ACC (*medium confidence*) (Section 9.2.4.2). As today, vertical land motion will remain a major driver of relative sea-level change (*high confidence*). Uncertainty in relative sea-level projections is greatest in tectonically active areas in which vertical land motion varies over short distances (e.g., Alaska) and in areas potentially subject to large ocean dynamic sea-level change (e.g., the northwestern Atlantic) (*high confidence*).

[START FIGURE 9.28 HERE]

Figure 9.28: Regional sea level change at 2100 for different scenarios (with respect to 1995-2014). Median regional relative sea-level change from 1995 to 2014 up to 2100 for (a) SSP1-1.9, (b) SSP1-2.6, (c) SSP2-4.5, (d) SSP3-7.0, (e) SSP5-8.5, and (f) width of the *likely* range for SSP3-7.0. The high uncertainty in projections around Alaska and the Aleutian Islands arises from the tectonic contribution to vertical land motion, which varies greatly over short distances in this region. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.28 HERE]

An alternative perspective on uncertainty in future sea-level rise is provided by looking at uncertainty in time rather than elevation; that is, looking at the range of dates when specific thresholds of sea-level rise are projected to be crossed (Figure 9.29). Considering only *medium confidence* processes, GMSL rise is *likely* to exceed 0.5 m between about 2080 and 2170 under SSP1-2.6 and between about 2070 and 2090 under SSP5-8.5. It is *likely* to exceed 1.0 m between about 2150 and some point after 2300 under SSP1-2.6, and between about 2100 and 2150 under SSP5-8.5. It is *unlikely* to exceed 2.0 m until after 2300 under SSP1-2.6, while it is *likely* to do so between about 2160 and 2300 under SSP5-8.5. However, processes in whose projections there is *low confidence* could lead to substantially earlier exceedances under higher emissions scenarios: under SSP5-8.5, 1.0 m could be exceeded by about 2080 and 2.0 m could be exceeded by about 2110 (17th percentile of p-box incorporating projections based on SEJ and MICI), with 5th percentile projections as early as about 2070 for 1.0 m and 2090 for 2.0 m.

[START FIGURE 9.29 HERE]

Figure 9.29: Timing of when GMSL thresholds of 0.5, 1.0, 1.5 and 2.0 m are exceeded, based upon four different ice-sheet projection methods informing post-2100 projections. Methods are labelled based on their

ACCEPTED VERSION SUBJECT TO FINAL EDITING

treatment of ice sheets. "No acceleration" assumes constant rates of mass change after 2100. "Assessed ice sheet" models post-2100 ice sheet losses using a parametric fit (Supplementary Material 9.SM.4) extending to 2300 based on a multimodel assessment of contributions under RCP2.6 and RCP8.5 at 2300. Structured Expert Judgement (SEJ) employs ice-sheet projections from Bamber et al. (2019) Marine Ice Cliff Instability (MICI) combines the parametric fit (Supplementary Material 9.SM.4) for Greenland with Antarctic projections based on (DeConto et al., 2021). Circles/thick bars/thin bars represent the 50th, 17th-83rd, and 5th-95th percentiles of the exceedance timing for the indicated projection method. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.29 HERE]

9.6.3.4 Sea-level projections up to 2100 based on global warming levels

Global warming levels represent a new dimension of integration in the AR6 cycle (Section 1.6.2, Cross-Chapter Box 11.1). The SR1.5 (Hoegh-Guldberg et al., 2018) concluded that, based upon an assessment of GMSL projections published for 1.5°C and 2.0°C scenarios, there is *medium agreement* that GMSL in 2100 would be 0.04 –0.16 m higher in a 2°C warmer world compared to a 1.5°C warmer world based on the 17–83% confidence interval (0.00 – 0.24 m based on the 5–95% confidence interval) with a value of around 0.1 m. The SR1.5 did not attempt to standardize the definition of warming-level scenarios, or to examine additional warming levels. No new integrated GMSL projections for 1.5°C or 2.0°C scenarios have been published since the SR1.5.

Most of the contributors to GMSL are more closely tied to time-integrated GSAT than instantaneous GSAT (Hermans et al., 2021), which means that sea level projections by warming level can only be interpreted if the warming levels are linked to a specific timeframe. Here, the warming level projections are defined based on the 2081-2100 GSAT anomaly (Supplementary Material 9.SM.4.7). Different pathways in GSAT can be followed to reach a certain temperature level, which affects the temporal evolution of the different contributors to sea-level change. For instance, there will be different ice sheet and glacier responses to a fast increase to a peak warming of 2°C in 2050 followed by a plateau or a decrease, compared to a gradual increase to the same level of warming in 2100. The sea-level projections presented might include different pathways to the same warming level in 2100, which is reflected in the uncertainty ranges, and should therefore be interpreted as an illustration of sea-level scenarios under a certain warming level.

Projections of *likely* 21st century GMSL rise along climate trajectories leading to different increases in GSAT between 1850-1900 and 2081-2100 are shown in Table 9.10, along with the SSPs for which the temperature-level projections are most closely aligned. For example, considering only processes in which there is *medium confidence*, from the baseline period (1995 to 2014) up to 2100, GMSL in a 2°C scenario is *likely* to rise by 0.40-0.69, which is intermediate between the projections for SSP1-2.6 and SSP2-4.5. GMSL in a 4°C scenario is *likely* to rise by 0.58-0.91 m, similar to the projection for SSP3-7.0. Consistent with the discussion in Section 9.6.3.3, there is *deep uncertainty* in the projections for temperature levels above 3°C, and alternative approaches to projecting ice sheet changes may yield substantially different projections in 4°C and 5°C futures. For example, employing SEJ (Bamber et al., 2019) ice-sheet projections instead of the projections for *medium confidence* processes only leads to a 17th-83rd percentile rise between the baseline period (1995-2014) and 2100 of 0.7-1.6 m rather than 0.7-1.1 m in a 5°C scenario.

[START TABLE 9.10 HERE]

Table 9.10: Global mean sea-level projections and commitments for exceedance of 5 global warming levels, defined by sorting GSAT change in 2081-2100 w.r.t. 1850-1900. Median values and (*likely*) ranges are in meters relative to a 1995-2014 baseline. Rates are in mm yr^{-1}. Unshaded cells represent processes in whose projections there is *medium confidence*. Shaded cells incorporate a representation of processes in which there is *low confidence*; in particular, the SSP5-8.5 *low confidence* column shows the 17th-83rd percentile range from a p-box including SEJ- and MICI-based projections rather than an assessed *likely* range. Methods are described in 9.6.3.2.

9.6.3.5 Multi-century and multi-millennial sea-level rise

Neither the AR5 nor the SROCC discussed the sea-level commitment associated with historical emissions. Since the AR5, new evidence has suggested that historical emissions up to 2016 will lead to a *likely* committed sea-level rise (i.e., the rise that would occur in the absence of additional emissions) of 0.7—1.1 m up to 2300, while pledged emissions through 2030 increase the committed rise to 0.8—1.4 m (Nauels et al., 2019).

Between the baseline period (1995 to 2014) and 2300, the AR5 projected a GMSL rise of 0.38-0.82 m under a non-specific low emissions scenario and 0.9-3.6 m under a non-specific high emissions scenario (Table 9.11). The SROCC projected 0.6-1.0 m under RCP 2.6 and 2.3-5.3 m under RCP 8.5 (*low confidence*). RCP-based projections for 2300 published since the AR5 span a broader range, even excluding studies employing SEJ or MICI, with 17-83rd percentile projections ranging from 0.3-2.9 m for RCP 2.6 and 1.7-6.8 m for RCP 8.5 (Kopp et al., 2014, 2017, Nauels et al., 2017, 2019; Bamber et al., 2019; Palmer et al., 2020) (Table 9.SM.8). Conservatively extending the ISMIP6- and LARMIP-2-based projections beyond 2100 by assuming no subsequent change in ice-sheet mass flux rates (an approach similar to that adopted by (Palmer et al., 2020) for the Greenland Ice Sheet and for the Antarctic Ice Sheet dynamics) leads to a GMSL change up to 2300 of 0.8-2.0 m under SSP1-2.6 and 1.9-4.1 m under SSP5-8.5 (17th-83rd percentile), while incorporating the ice-sheet contributions for 2300 assessed in Section 9.4.1.4 and Section 9.4.2.6 leads to 0.6-1.5 m and 2.2-5.9 m, respectively. Incorporating Antarctic results from a model with Marine Ice Cliff Instability (Section 9.4.2.4), using RCP forcing to inform SSP-based projections, leads to 1.4-2.1 m for SSP1-2.6 and 9.5-16.2 m for SSP5-8.5 (DeConto et al., 2021). Incorporating the SEJ-based ice-sheet projections of (Bamber et al., 2019) for 2°C and 5°C stabilization scenarios yields 1.0-3.1 m for SSP1-2.6 and 2.4-6.3 m for SSP5-8.5, though because of the differences in scenarios, the SSP1-2.6 estimates may be overestimated and the SSP5-8.5 may be underestimated. The eight-fold uncertainty range across projection methods under SSP5-8.5 reflects *deep uncertainty* in the multi-century response of ice sheets to strong climate forcing.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Taking into account all these approaches, including published projections for RCP 2.6, under SSP1-2.6 GMSL will rise between 0.3 and 3.1 m by 2300 (*low confidence*). This projection range indicates that, while the SROCC projections under low emissions to 2300 are consistent with no ice sheet acceleration after 2100, there is the possibility of a much broader range of outcomes at the high end, reflected in the range of published GMSL projections. Under SSP5-8.5, GMSL will rise between 1.7 and 6.8 m by 2300 in the absence of MICI and by up to 16 m considering MICI, a wider range than the AR5 or the SROCC assessments but consistent with published projections (*low confidence*).

[START TABLE 9.11 HERE]

Table 9.11: Global mean sea-level projections between 1995-2014 and 2300 for total change and individual contributions, for low emissions (from the AR5 (Church et al., 2013b)), RCP 2.6 (from the SROCC (Oppenheimer et al., 2019), and published projections (Table 9.SM.8)) and SSP1-2.6 (this report), and for high emissions (from the AR5(Church et al., 2013b)), RCP 8.5 (from the SROCC (Oppenheimer et al., 2019), and published projections (Table 9.SM.8)), and SSP5-8.5 (this report). Values for the AR5 (Church et al., 2013b) and the SROCC (Oppenheimer et al., 2019) are adjusted from the 1986-2005 baseline used in past reports. Only total values are shown for published ranges. Only the Antarctic contribution changed between the AR5 (Church et al., 2013b) and the SROCC (Oppenheimer et al., 2019). If a range is given it is the 17th—83rd percentile range.

[END TABLE 9.11 HERE]

On still longer timescales, the AR5 concluded with *low confidence* that the multi-millennial GMSL commitment sensitivity to warming was about 1 to 3 m°C^{-1} GSAT increase. Two process-model-based studies since the AR5 (Clark et al., 2016; Van Breedam et al., 2020) indicate higher commitments (Figure 9.30). Ice sheets dominate the multi-millennial sea-level commitment (Sections 9.4.1.4, 9.4.2.6), but the two studies disagree on the relative contribution of the Greenland and Antarctic ice sheets. Notably, processes such as Marine Ice Cliff Instability (Section 9.4.2.4) that are a major factor behind the *deep uncertainty* in century-scale Antarctic ice sheet response do not appear to have a substantial effect on the multimillennial magnitude (DeConto and Pollard, 2016). Only one of the studies of multimillennial GMSL commitments includes scenarios consistent with 1.5°C of peak warming (Clark et al., 2016); this study suggests a 2000-year commitment at 1.5°C of about 2.3-3.1 m, with approximately an additional 1.4-2.3 m commitment between 1.5°C and 2.0°C (i.e., about 3 to 5 m °C^{-1}). Taken together, both studies show a 2000-year GMSL commitment of about 2-6 m for peak warming of about 2°C, 4-10 m for 3°C, 12-16 m for 4°C, and 19-22 m for 5°C (*medium agreement, limited evidence*, Table 9.10). GMSL rise continues after 2000 years, leading to a 10,000-year commitment of about 6-7 m for 1.5°C of peak warming (based on (Clark et al., 2016)), and of about 8-13 m for 2.0°C, 10-24 m for 3.0°C, 19-33 m for 4.0°C, and 28-37 m for 5°C (based on both studies) (*medium agreement, limited evidence*, Table 9.10).

[START FIGURE 9.30 HERE]

Figure 9.30: Global mean sea-level commitment as a function of peak global surface air temperature. From models (Clark et al., 2016; DeConto and Pollard, 2016; Garbe et al., 2020; Van Breedam et al., 2020) and paleo data on 2000-year (lower row) and 10,000 year (upper row) timescales. Columns indicate different contributors to GMSL rise (from left to right: total GMSL change, Antarctic Ice Sheet, Greenland Ice Sheet, global mean thermosteric sea-level rise, and glaciers). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.30 HERE]

An indicative metric for the equilibrium sea-level response can be provided by comparing paleo global surface air temperature and GMSL during past multimillennial warm periods (Sections 2.3.1.1, 2.3.3.3 9.6.2, Figure 9.9). However, caution is needed as the present and past warm periods differ in astronomical and other forcings (Cross-chapter Box 2.1) and in terms of polar amplification. The Last Interglacial (*likely* 5-10 m higher GMSL than today and 0.5-1.5°C warmer than 1850-1900; Section 9.6.2; Table 9.6) is consistent with the (Clark et al., 2016) projections for the 10,000-year commitment associated with 1.5°C of warming. Similarly, the Mid-Pliocene Warm Period (*very likely* 5-25 m higher GMSL than today and *very likely* 2.5-4°C warmer; Section 9.6.2; Table 9.6) is consistent with the range of 10,000 year commitments associated with 2.5-4°C of warming, but GMSL reconstructions provide only a weak, broad constraint on model-based projections. An additional paleo constraint comes from the Early Eocene Climatic Optimum, which indicates that 10-18°C of warming is associated with ice-free conditions and a *likely* GMSL rise of 70-76 m (Section 2.3.3, Section 9.6.2). Together with model-based projections (Clark et al., 2016; Van Breedam et al., 2020), this period suggests that commitment to ice-free conditions would occur for peak warming of about 7 - 13°C (*medium agreement, limited evidence*).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

On the basis of modeling studies, paleo constraints, single-ice sheet studies finding multimillennial nonlinear responses from both the Greenland and Antarctic ice sheets (Sections 9.4.1.4, 9.4.2.6), and the underlying physics, we conclude that GMSL commitment is nonlinear in peak warming on timescales of both 2,000 and 10,000 years (*medium confidence)* and exceeds the AR5 assessment of 1 to 3 m $°C^{-1}$ (*medium agreement, limited evidence*) (Table 9.9). Although thermosteric sea level will start to decline slowly about 2,000 years after emissions cease, the slower responses from the Greenland and Antarctic ice sheets mean that GMSL will continue to rise for 10,000 years under most scenarios (*medium confidence*).

Since the AR5, a small number of modelling studies have examined the reversibility of the multimillennial sea-level commitment under carbon dioxide removal, solar radiation modification or local ice-shelf engineering. The slow response of the deep ocean to forcing leads to global-mean thermosteric sea-level fall occurring long afterward even if CO_2 levels are restored after a transient increase: global mean thermosteric sea level takes over a millennium to reverse course (Ehlert and Zickfeld, 2018b). Rapid reversion to pre-industrial CO_2 concentrations has been found to be ineffective at fostering regrowth of the Antarctic ice sheet (DeConto et al., 2021) but may reduce the multimillennial sea-level commitment (DeConto and Pollard, 2016). Altering sub-ice shelf bathymetry (Wolovick and Moore, 2018) or triggering ice-shelf advance through massive snow deposition (Feldmann et al., 2019) might interrupt Marine Ice Sheet Instability (Section 9.4.2.4) and thus reduce sea-level commitment. A reversion to pre-industrial Greenland ice sheet temperatures with solar radiation modification is projected to stop mass loss in Greenland but leads to minimal regrowth (Applegate and Keller, 2015). Based on *limited evidence*, carbon dioxide removal, solar radiation modification, and local ice-shelf engineering may be effective at reducing the yet-to-be-realized sea-level commitment but ineffective at reversing GMSL rise (*low confidence*).

[START BOX 9.4 HERE]

BOX 9.4: High-end storyline of 21st century sea-level rise

In this box, we outline a storyline (Glossary, Box 10.2 (Shepherd et al., 2018)) for high-end sea-level projections for 2100. This storyline considers processes whose quantification is highly uncertain regarding the timing of their possible onset and/or their potential to accelerate sea-level rise. These processes are therefore not considered for the assessed upper bound of *likely* sea-level rise by 2100 in section 9.6.3.3, as the *likely* range includes only processes that can be projected skilfully with at least *medium confidence* (based on *agreement* and *evidence)*.

As noted by the SROCC, stakeholders with a low risk tolerance (e.g., those planning for coastal safety in cities and long-term investment in critical infrastructure) may wish to consider global-mean sea-level rise above the assessed *likely* range by the year 2100, because "*likely*" implies an assessed likelihood of up to 16 % that sea-level rise by 2100 will be higher (see also (Siegert et al., 2020)). Because of our limited understanding of the rate at which some of the governing processes contribute to long-term sea-level rise, we cannot currently robustly quantify the likelihood with which they can cause higher sea-level rise before 2100 (Stammer et al., 2019).

In light of such *deep uncertainty*, we employ a storyline approach in examining the potential for, and early-warning signals of a high-end sea-level scenario unfolding within this century. In doing so, we note upfront that the main uncertainty related to high-end sea-level rise is "when" rather than "if" it arises: the upper limit of 1.02 m of *likely* sea-level range by 2100 for the SSP 5-8.5 scenario will be exceeded in any future warming scenario on time scales of centuries to millennia (*high confidence*), but it is uncertain how quickly the long-term committed sea level will be reached (Section 9.6.3.5). Hence, global-mean sea level might rise well above the *likely* range before 2100, which is reflected by assessments of ice-sheet contributions based on structured expert judgment (Bamber et al., 2019) leading to a 95th percentile of projected future sea-level rise as high as 2.3 m in 2100 (Section 9.6.3.3).

A plausible storyline for such high-end sea-level rise in 2100 assumes a strong warming scenario (Section 4.8). The storyline considers faster-than-projected disintegration of marine ice shelves and the abrupt,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

widespread onset of Marine Ice Cliff Instability (MICI) and Marine Ice Sheet Instability (MISI) in Antarctica (Section 9.4.2.4), and faster-than-projected changes in both the surface mass balance and dynamical ice loss in Greenland. While conceptual studies provide *medium evidence* of these processes, substantial uncertainties and *low agreement* in quantifying their future evolution arise from limited process understanding, limited availability of evaluation data, missing or crude representation in model simulations, their high sensitivity to uncertain boundary conditions and parameters, and/or uncertain atmosphere and ocean forcing (Sections 9.4.1.2; 9.4.2.2).

In Antarctica, high warming might lead to floating ice shelves starting to break up earlier than expected due to processes not yet accounted for in ice-sheet models or in current climate models used to force ice-sheet projections. Such processes include hydrofracturing driven by surface meltwater and increase in ocean thermal forcing driven by ocean circulation changes (Sections 9.2.2.3, 9.2.3.2, 9.4.2.3) (Hellmer et al., 2012, 2017; Silvano et al., 2018; Hazel and Stewart, 2020). In particular, the Thwaites and Pine Island Glacier ice shelves could potentially disintegrate this century, which might trigger MICI before 2100 (DeConto and Pollard, 2016; DeConto et al., 2021). MISI could potentially develop earlier and faster than simulated by the majority of models if fast flowing ice streams follow plastic, instead of currently assumed more viscous, sliding laws (Sun et al., 2020). Oceanic feedbacks could drive high-end sea-level rise by changes in the meltwater-driven overturning circulation in ice cavities that cause additional melting (Jeong et al., 2020); by a warming of the ocean water in contact with the ice shelves due to increased stratification and thus reduced vertical mixing (Sections 9.2.2.3, 9.2.3.2) (Golledge et al., 2019b; Moorman et al., 2020; Sadai et al., 2020); or by an increase in sea-ice cover due to increased ocean stratification (Section 9.3.2.1), which could reduce the amount of warm, moist air that reaches the continent and limit the mass gain from snowfall over the ice sheet (Sadai et al., 2020).

In Greenland, stronger mass loss than currently projected might also occur (Aschwanden et al., 2019; Khan et al., 2020; Slater et al., 2020b). For example, warming-induced dynamical changes in atmospheric circulation could enhance summer blocking and produce more frequent extreme melt events over Greenland similar to the record mass loss of more than 500 Gt in summer 2019 (Section 9.4.1.1) (Delhasse et al., 2018; Sasgen et al., 2020). Cloud processes in polar areas that are not well represented in models could further enhance surface melt (Hofer et al., 2019), as could feedbacks between surface melt and the increasing albedo from meltwater, detritus and pigmented algae (Section 9.4.1.1) (Cook et al., 2020). The same ice dynamical processes associated with basal melt and MISI discussed for Antarctica could also occur in Greenland as long as the ice sheet is in contact with the ocean.

The strength of all these processes is currently understood to depend strongly on global mean temperature and polar amplification, with additional linkages through feedback from global mean sea-level (Gomez et al., 2020). These dependencies on a joint forcing imply that processes are strongly correlated. Hence, both their uncertainties and their possible cascading contribution to high-end sea-level rise are expected to combine. High-end sea-level rise can therefore occur if one or two processes related to ice-sheet collapse in Antarctica result in an additional sea-level rise at the maximum of their plausible ranges (Sections 9.4.2.5, 9.6.3.3; Table 9.7) or if several of the processes described in this box result in individual contributions to additional sea-level rise at moderate levels. In both cases, global-mean sea-level rise by 2100 would be substantially higher than the assessed *likely* range, as indicated by the projections including *low confidence* processes reaching in 2100 as high as 1.6 m at the 83rd percentile and 2.3 m at the 95th percentile (Section 9.6.3.3).

Identifying the potential drivers of a high-end sea-level rise allows identification of sites and observables that can provide early warnings of a much faster sea-level rise than the *likely* range of this and previous reports. One potential site for such monitoring is Thwaites Glacier, which is melting faster in some places and slower in others than models simulate. At this glacier, the effect of tides and channelling of warm water flows on the melting is evident (Milillo et al., 2019), making the floating ice shelf potentially vulnerable to breakup from hydrofracturing, driven by surface meltwater, much earlier than expected. In addition, the glacier is retreating towards a zone with deeper bedrock, which at its present rate of retreat would be reached in 30 years (Yu et al., 2019). Thwaites Glacier is therefore a strong candidate to experience large-scale MISI and/or MICI (Golledge et al., 2019b; DeConto et al., 2021), making it the ideal site for monitoring early-warning signals of accelerated sea-level-rise from Antarctica. Such signals could possibly be observed within

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the next few decades (Scambos et al., 2017).

[END BOX 9.4 HERE]

9.6.4 Extreme sea levels: Tides, surges and waves

An extreme sea level (ESL) refers to an occurrence of exceptionally high or low local sea surface height (Box 9.1). This section focusses on oceanographic driven changes in ESL (Box 9.1).

9.6.4.1 Past changes

The AR5 (Church et al., 2013a) concluded that changes in extreme still water levels (ESWL, combining relative sea level, tide and surge as observed by tide gauges: Box 9.1) are *very likely* to be caused by observed increases in relative sea level, but noted *low confidence* in region-specific results owing to the limited number of studies considering localised contributions from storm surge, tide or wave effects. Influences from dominant modes of climate variability, particularly ENSO and NAO (Annex IV), were also noted. Climate modes affect sea level extremes in many regions, as a result of both sea-level anomalies (Sections 9.2.4.2, 9.6.1.3) and changes in storminess (Section 11.7). The SROCC (Oppenheimer et al., 2019) concluded with *high confidence* that inclusion of local processes (wave effects, storm surges, tides plus other regional morphology changes due to erosion, sedimentation and compaction) is essential for estimation of changes in ESL events.

As in the AR5 and the SROCC, tide gauge observations show that relative sea level rise (Section 9.6.1.3) is the primary driver of changes in ESWL at most locations and, across tide gauges, has led to a median 165% increase in high-tide flooding over 1995-2014 relative to those over 1960-1980 (Figure 9.31) (*high confidence*). Some locations exhibit substantial differences between long-term relative sea level trends and ESWL (*high confidence*), particularly given decadal to multidecadal variations of other ESWL contributors (Rashid and Wahl, 2020). Since the SROCC, relative sea level rise has been shown to be the dominant contributor to ESWL rise at most gauge sites along the Chinese coast, but, at some locations, the surge contribution dominates (Feng et al., 2019). Trends in the difference between ESWL and mean relative sea level rise can result from changes (either positive or negative) in the surge or tidal components, and can include non-linear interactions between tide, surge, and relative sea level (Arns et al., 2015; Schindelegger et al., 2018). The positive phase of the 18.6 year nodal cycle of the astronomical tide is a further consideration, contributing to an increased flood hazard relative to the long term average (Talke et al., 2018; Peng et al., 2019; Baranes et al., 2020). Failing to consider the non-linear interactions between tide, surge and relative sea level may overestimate trends in ESWL (Arns et al., 2020) (*low confidence*), and, in some regions, changes in ESWL depend more on changes in surge or tide than on sea level trends.

Ongoing development of the GESLA tide gauge database (Woodworth et al., 2016) along with data archaeology (Talke and Jay, 2013) extends availability of tide gauge records back to the mid 19th Century (or earlier). Dynamical datasets used to assess trends in ESL at global or regional scales (e.g., tide and surge contributions from the Global Tide and Surge Reanalysis (GTSR) (Muis et al., 2016, 2020), or wave setup/swash contributions from available wave hindcasts/reanalyses (Melet et al., 2018)) have model biases introduced with resolution and parameterisation limitations, incomplete atmospheric data and currently span only a few decades, so they are not yet long or accurate enough to assess long-term trends in ESLs. Therefore, there is *medium confidence* in observed trends in ESWL but only *low confidence* in modelled ESL trends.

The AR5 indicated that the amplitude and phase of major tidal constituents have exhibited long-term change, but that their effects on ESL were not well understood. The SROCC (Bindoff et al., 2019) reported changes in tides (amplification and dampening) at some locations to be of comparable importance to changes in mean sea level for explaining changes in high water levels, with the sign of change being dependent on stability of shoreline position. Relative sea level rise causes water depth-based alterations to the resonant characteristics

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of the basin, changes the bottom friction and increases the wave speed (Pickering et al., 2012) and remains the primary hypothesis for observed tidal changes. Other contributing processes include strong localised anthropogenic drivers (e.g., port development, dredging, flood defences, land reclamation), changes in stratification associated with ocean warming (Section 9.2.1.3), and changes in seabed roughness associated with ecological change (e.g., Haigh et al., 2019). Tide gauge data show that, although principal tidal components have varied in amplitude on the order of 2% to 10% per century (Jay, 2009; Ray, 2009), identifying direct causality remains challenging (Haigh et al., 2019). Combined, observations and models indicate relative sea level rise and direct anthropogenic factors are the primary drivers of observed tidal changes at tide gauge stations (*medium confidence*).

The SROCC (Oppenheimer et al., 2019) reported variations in storm surge not related to changes in relative sea level, and concluded with *high confidence* that consideration of localised storm surge processes was essential to monitor trends in ESL. Storm surge-driven ESL events are a response to tropical and extratropical cyclones. While historical trends in extra-tropical cyclones are less clear (Section 11.7.2.1), there is mounting evidence for an increasing proportion of stronger tropical cyclones globally, with an associated poleward migration (Section 11.7.1.2). These changes are captured in the ESL record, for example, via increasing intensity and poleward shift in the location of typhoon-driven storm surges reported across 64 years (1950-2013) in the western North Pacific (Oey and Chou, 2016). Along the US east coast, there has been an increase in frequency of ESL events due to tropical cyclone changes since 1923 that can be statistically linked to changes in global average temperature (Grinsted et al., 2013), and the signal is projected to emerge around 2030 (Lee et al., 2017). At century and longer timescales, geological proxies such as overwash deposits in coastal lagoons or sinkholes can be used to reconstruct past changes in storm activity (e.g., Brandon et al., 2013; Lin et al., 2014) and put recent events into historical perspective (e.g., Brandon et al., 2015). However, there is *low confidence* in the current ability to quantitatively compare geological proxies with gauge data. Historical storm surge activity is being increasingly assessed with use of hydrodynamic model simulations and data-driven global reconstructions to supplement tide-gauge observations to investigate historical changes at centennial to millennial time scales (e.g., (Ji et al., 2020; Muis et al., 2020; Tadesse et al., 2020). Large regional variations and limited observational data lead to *low confidence* in observed trends in the surge contribution to increasing ESL.

[START FIGURE 9.31 HERE]

Figure 9.31: Historical occurrences of minor extreme still water levels. Defined as the 99th percentile of daily observed water levels over 1995-2014. (a) Percent change in occurrences over 1995-2014 relative to those over 1960-1980. (b-g) Annual mean sea level (blue) and annual occurrences of extreme still water levels over the 1995-2014 99th percentile daily maximum (yellow) at six selected tide gauge locations. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

[END FIGURE 9.31 HERE]

Waves contribute to ESL via wave setup, infra-gravity waves and swash processes (Dodet et al., 2019), with Extreme Total Water Level (ETWL: Box 9.1) used to represent ESWL with addition of wave setup, and Extreme Coastal Water Level (ECWL: Box 9.1) also including contributions from swash. The SROCC (Oppenheimer et al., 2019) reported the dependency of these processes on nearshore geomorphology and deep-water wave climate, and thus sensitivity to internal climate variability and climate change. Few long term deployments of in-situ measurements in the very dynamic surf zone means that long term records of ETWL or ECWL are limited to a few sites; tidal gauges are typically located in sheltered locations (e.g., harbours) where wave contributions are absent (Lambert et al., 2020). Consequently, trends in wave contributions to ESL are typically derived from trends in wave conditions observed offshore. On the basis of satellite altimeter observations, the SROCC reported increasing extreme wave heights in the Southern and North Atlantic Oceans of around 1.0 cm yr^{-1} and 0.8 cm yr^{-1} over the period 1985-2018 (*medium confidence*). The SROCC (Collins et al., 2019) also identified sea-ice loss in the Arctic as leading to increased wave heights over the period 1992 to 2014 (*medium confidence*). Since the SROCC, the satellite wave record has

ACCEPTED VERSION SUBJECT TO FINAL EDITING

been shown to be sensitive to alternate processing techniques, leading to important differences in reported trends (Timmermans et al., 2020). The most common observation platform for surface waves over the past 30 years are in-situ buoys. However, evolving biases associated with changing instrument type, configuration and sampling methodology introduce artificial trends (e.g., Gemmrich et al., 2011; Timmermans et al., 2020). Accurate metadata is required to address these issues, and, while available locally, are only beginning to be globally coordinated (Centurioni et al., 2019). Wave reanalysis and hindcast products have also been used to investigate total water level at global scale (Melet et al., 2018; Reguero et al., 2019). Their applicability for trend analysis is limited by inhomogeneous data for assimilation (Stopa et al., 2019), but they inform relationships between seasonal, inter-annual to inter-decadal variability of climate indices and wind-wave characteristics (Marshall et al., 2015a, 2018; Kumar et al., 2016; Stopa et al., 2016). To summarise, satellite era trends in wave heights of order 0.5 cm yr^{-1} have been reported, most pronounced in the Southern Ocean. However, sensitivity of processing techniques, inadequate spatial distribution of observations, and homogeneity issues in available records limit confidence in reported trends (*medium confidence*).

Only a few studies have attempted to quantify the role of anthropogenic climate change in ESL events (e.g. Mori et al., 2014, Takayabu et al., 2015, Turki et al., 2019). Detection and attribution of the human influence on climatic changes in surges, and waves remains a challenge (Ceres et al., 2017), with *limited evidence* to suggest in some instances (e.g., poleward migration of tropical cyclones in the Western North Pacific: Section 11.7.1.2), changes in surges and waves can be attributed to anthropogenic climate change (*low confidence*). With relative sea-level change being considered the primary driver of observed tidal changes, there is *medium confidence* that these changes can be attributed to human influence. The close relationship between local ESL and long-term relative sea level change, combined with the robust attribution of GMSL change (Section 9.6.1.4), implies that observed global changes in ESL can be attributed, at least in part, to human-caused climate change (*medium confidence*), but reconciling regional variation in these changes is not yet possible (Section 9.6.1.4).

9.6.4.2 Future changes

There are two distinct methods used to project future ESL changes. The static, or mean sea level offset, approach employs historical distributions of tidal, surge and wave components and adjusts future ESL distributions for mean relative sea level rise. The dynamic approach employs hydrodynamic and/or wave models forced with GCM-derived atmospheric fields to project changes in tidal, storm surge and wave distributions, which are then combined with relative sea level projections to project future ESLs. The dynamic approach is computationally expensive. Use of the dynamic approach on large spatial or global scales has only recently been successful to project 21st Century changes in ETWL (Vousdoukas et al., 2017, 2018) and ECWL (Melet et al., 2020). (Kirezci et al., 2020) assume stationarity in global wave and storm surge simulations to assess projected 21st century changes in episodic coastal ETWL driven flooding under global sea-level rise scenarios.

The SROCC (Oppenheimer et al., 2019) presents projections of ESL derived using a static approach. Such projections often quantify changes in ESL event frequency, expressed as “frequency amplification factors” (Hunter, 2010, 2012). Like relative sea level projections, frequency amplification factors increase under higher emission scenarios, and differences between scenarios increase over time. The SROCC concludes that even small to moderate changes in mean relative sea level can lead to hundred- to thousand-fold increases in the frequencies with which certain thresholds are exceeded; e.g., what is currently a 1-in-100 year ESL height (1% annual probability or 0.01 expected annual events) will be expected once or even multiple times per year in future at many locations (Figure 9.32). The SROCC showed that currently rare ESL events (e.g., with an average return period of 100 years) will occur annually or more frequently at most available locations for RCP4.5 by the end of the century (*high confidence*). Results from these assessments are sensitive to the type of ESL probability distribution assumed (Buchanan et al., 2016; Wahl et al., 2017), as well as the magnitude and uncertainty of projected relative sea level change (Slangen et al., 2017; Wahl et al., 2017; Frederikse et al., 2020a). Frequency amplification factors tend to be largest in tropical regions due in part to higher relative sea level rise projections, but primarily to the relative rarity of high ESLs in areas

ACCEPTED VERSION SUBJECT TO FINAL EDITING

with little historical exposure to tropical or extratropical cyclones. Alternative representation of changes in ESL, such as presenting changes in exceedances per year (Sweet and Park, 2014), are subject to similar sensitivities, and lead to *medium confidence* in projected changes of event frequency using these methods.

Employing a similar static approach (fitting a Gumbel distribution between Mean Higher High Water (average of higher high water height of each tidal day) and a threshold following (Buchanan et al., 2016)), this report updates the SROCC projections of ESL with the relative sea level projections from Section 9.6.3.3 (see also Supplementary Material 9.SM.4). By 2050, the median increase in frequency amplification factor at 634 tide gauge stations is 19 for SSP1-2.6, 22 for SSP2-4.5 and 30 for SSP5-8.5 (Figure 9.32). This means that by 2050 a historical (1995-2014) 1% annual probability ESL will have increased to an 19-30% annual probability. The 1% historical annual probability event is expected to become an annual event at 19-31% of the 634 stations by 2050, consistent with the SROCC. By 2100, the median frequency amplification factor is projected to be 163 for SSP1-2.6, 325 for SSP2-4.5 and 532 for SSP5-8.5, with respectively 60%, 71%, and 82% of the stations experiencing a currently 1% annual probability event at least yearly (Figure 9.32) (*medium confidence*).

In the dynamic approach, the low resolution of the forcing fields arising from GCMs limits the ability to resolve historical and future changes in tropical and extra-tropical storm frequency and intensity, and resolution of local geography and morphology limit ability to represent ECWL (Box 9.1). Not all relevant processes, e.g., river discharge, are included in the dynamic models, and ESL events are typically a combination of multiple contributing processes, which are often not independent (Jevrejeva et al., 2019). In both static and dynamical approaches, global assessment of the performance of modelled storm surge and wave contributions to ESL is limited by poor coverage of observations (limited to tide-gauges for ESWL, (Muis et al., 2020), and unavailable for the wave dependent ETWL and ECWL estimates (Vitousek et al., 2017; Vousdoukas et al., 2018; Kirezci et al., 2020; Lambert et al., 2020; Melet et al., 2020). In studies to date, individual models are used to simulate different contributions to ESL, non-linear interactions are not well captured, and uncertainties associated with downscaling methodology are poorly resolved, leading to *low confidence* in available ESL projections that include these modelled wave and surge contributions.

Assessment of dynamic ETWL changes for regions is presented in Chapter 12, following the methods of (Vousdoukas et al., 2018) and (Kirezci et al., 2020). Consistent with studies using the static approach, (Vousdoukas et al., 2018) finds that by 2050 the historical 1% average annual probability ETWL will have increased to a 2-50% average annual probability for most high latitude regions, and more often (up to multiple times a year, >100% annual probability) in the tropics, under both RCP 4.5 and RCP 8.5. For 2100, present-day 1% average annual probability extreme sea levels will be exceeded multiple times each year almost everywhere. In summary, despite waves and surges being non-negligible contributors to projected ETWL and ECWL changes (Vousdoukas et al., 2018; Melet et al., 2020), relative sea level change is expected to be the main driver in changes in future ESL return periods in most areas (*medium confidence)*.

The SROCC (Bindoff et al., 2019) concluded that the majority of coastal regions will experience statistically significant changes in tidal amplitudes through the 21st Century. Comprehensive high-resolution (of order 10km) numerical modelling studies provide evidence for spatially coherent changes in tidal amplitudes in shelf seas as a result of relative sea level rise (Haigh et al., 2019, and references therein). There is *high confidence* that GMSL rise will be the primary driver of global tidal amplitude increases and decreases over the next 100-200 years, changing the baseline tide that ESLs are imposed upon. At local and regional scales, anthropogenic factors such as major land reclamation efforts (e.g., East China Sea, Song et al., 2013) or differing national coastal management strategies (maintaining the present coastline position or managed retreat) will locally modulate the influence of GMSL rise on tidal amplitude (*medium confidence*).

The SROCC (Oppenheimer et al., 2019) concluded that the intensity of severe tropical cyclones will increase in a warmer climate (Section 11.7.1), but *low confidence* remains in the future frequency of tropical cyclones. Changes in tropical cyclone climatology will contribute to variations in frequency and magnitude of future ESL surge events, although estimates of this contribution range widely (Lin et al., 2012; McInnes et al., 2014, 2016; Little et al., 2015; Garner et al., 2017; Mori et al., 2019; Muis et al., 2020). In the Gulf of Mexico, changes in ESL due to tropical cyclone activity may be as important as SLR in enhancing future

ACCEPTED VERSION SUBJECT TO FINAL EDITING

flood hazards (Marsooli et al., 2019). For the Korean Peninsula, a maximum change in 100-year return height associated with typhoon-induced storm surges of 10% under 4°C warming is found (Yang et al., 2018). The effects of projected changes in tropical cyclone intensity may be enhanced or offset in different locations by effects of changes in tracks (Garner et al., 2017) (Section 11.7.1). There is *low confidence* in projected changes in ESL driven by changes in tropical cyclone climatology.

Changes in surface wave conditions occur in response to changes in frequency; intensity and position of forcing winds and storms (Morim et al., 2018, 2019); reduction in sea-ice and associated changes in fetch conditions (Thomson and Rogers, 2014; Casas-Prat and Wang, 2020); and changes in coastal morphology associated with relative sea level rise (Wandres et al., 2017; Storlazzi et al., 2018). A few studies considering the contribution of a non-stationary wave climate on future changes in ESL infer a small but non-negligible contribution (Vousdoukas et al., 2018; Melet et al., 2020). The SROCC presented qualitative assessments of projected changes in wave conditions. Since the SROCC, a quantitative assessment of a community ensemble of global wind-wave projections (Morim et al., 2019) found robust projected changes of ~5-10% (positive or negative, depending on region) in annual mean significant wave height, mean wave period, and/or mean wave directions along ~52% of the world's coastline that exceed internal climate variability under RCP8.5 by 2100. Continued retreat of sea-ice cover in the Arctic will lead to more energetic wind-wave conditions (Casas-Prat and Wang, 2020). Wave climate modelling methods introduce up to ~50% of the ensemble variance in mean wave climate projections (Morim et al., 2019). GCMs do not typically resolve the higher-resolution tropical and extratropical storm features required to accurately determine the contribution of extreme waves to ESLs and individual studies have sought to improve resolution to address these issues (e.g., Timmermans et al., 2017). To date, projections of wave height extremes have been constrained to single wave model configurations (e.g., Timmermans et al., 2017; Meucci et al., 2020). In summary, there is *medium confidence* in projections of changes in mean wave climate but *low confidence* in the projected changes in extreme wave conditions due to *limited evidence*.

Correlations between changes in sea level-forced (mean sea level and tidal) and atmospherically-forced drivers (ocean surface waves and surges) of ESLs have only been considered in a few studies, although high surge and high waves co-occur along a majority of the world's coastlines (Marcos et al., 2019). Along the US east coast, ocean dynamic sea level change and change in power dissipation index (a proxy for North Atlantic tropical cyclone activity) are correlated across CMIP5 GCMs, resulting in an increase in ESLs relative to analyses assuming independence of these changes (Little et al., 2015). In the Irish Sea, dynamically coupled wave-tide modelling results in high water wave heights up to 20% higher than in an uncoupled analysis (Lewis et al., 2019). In the German Bight, relative sea level rise relaxes the breaking criterion of nearshore waves (assuming no geomorphological response), allowing larger waves to propagate closer to shore, leading to increased wave runup (Arns et al., 2017). In south-western Australia, the influence of projected SLR was found to exceed the influence of projected changes in forcing winds on wave characteristics at the coast (Wandres et al., 2017). Thus, projections of ESL that do not consider correlations between and among sea level-forced and atmospherically-forced drivers can differ strongly from coupled projections (*medium confidence*).

The SROCC (Collins et al., 2019b) highlighted compound events, or coincident occurrence of multiple hazards, as an example of *deep uncertainty*, and noted that failing to account for multiple factors contributing to extreme events will lead to underestimation of the probabilities of occurrence (*high confidence*). Statistical studies have shown that high rain or streamflow often co-occurs with storm surge as examples of "compound" surge-rain or surge-discharge events (Sections 11.8.1; 12.4.5.6; Wahl and Chambers, 2015; Moftakhari et al., 2017; Ward et al., 2018; Wu et al., 2018; Couasnon et al., 2019). Dynamical modelling studies show co-occurrence of flood drivers raises ESLs at some locations in estuaries (e.g., Rhine Delta, Zhong et al., 2013; the Netherlands, van den Hurk et al., 2015; Taiwan, Chen and Liu, 2016; and the Hudson River, USA Orton et al., 2018), particularly when hydrologic catchments are steep and cause high rainfall near the coast (SW UK, Svensson and Jones, 2004). The compound effect of storm surge and rainfall contributes greater projected flood risk than climate induced amplification (Hsiao et al., 2021). However, at other locations, co-occurrence was unimportant because streamflow timing was not coincident with the coastal peak storm surge (Hudson River, Orton et al., 2012; Rhine delta, Klerk et al., 2015). The SROCC (Oppenheimer et al., 2019) detailed the complexity of interactions in deltaic environments. Direct increases

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in flooding driven by increasing relative sea levels and by increased storm surge, rain, or correlations between these flood-drivers (e.g., Moftakhari et al., 2017; Orton et al., 2018) are expected to be further accompanied by increases in flooding due to subsidence (vertical land movement) and sedimentation (relative sea level driven blockage of river flows). The probability of concurrent surge, wave and precipitation events has been projected to increase by more than 25% by 2100 compared to present, with high northern latitudes displaying compound flooding becoming more than 2.5 times as frequent, and weakening in the subtropics (Bevacqua et al., 2020). However, the number of studies on compound events is still limited and therefore there is *low confidence* in understanding the extent by which compound surge-rain events will change in response to relative sea level rise and climate change.

9.7 Final Remarks

The process-based assessment of observed and projected change in the ocean, cryosphere and sea level undertaken here reveals advances and gaps in reconstructions, observations, models and process understanding. Revisiting the updated assessments since the AR5 and the SROCC helps to gauge the robustness of understanding and quantitative assessments. The CMIP6 family of models builds upon the experience of the CMIP5 models, and the projections of ISMIP6, LARMIP2 and GlacierMIP strengthen understanding. Taken together with emulators of these simulations (Box 9.3) and transparent statistical approaches (Section 9.6.3), this chapter provides projections which are consistent with the assessment of Equilibrium Climate Sensitivity in this report and that have improved estimates of uncertainty.

The largest uncertainties in future sea level and cryosphere change are related to the Greenland and Antarctic ice sheets (Sections 9.4.1.3, 9.4.1.4, 9.4.2.5, 9.4.2.6). While the ISMIP6 and LARMIP2 protocols provide simulations permitting uncertainty estimation and probabilistic inferences, remaining *deep uncertainty* relates both to ice sheet processes and the atmospheric and oceanic conditions simulated by CMIP models in polar regions (Sections 9.4.2.3, 9.4.2.4). ISMIP6 and LARMIP2 have not been simulated beyond 2100, which greatly reduces the amount and variety of state-of-the-art projections available to make ice sheet and sea level projections beyond 2150. After 2150, *limited agreement* causes us to consider all projections as *low confidence*. Critically, the uncertainty in ice sheet projections is the leading uncertainty in projections of future global sea level for the second half of this century and beyond (Section 9.6.3).

Glacier inventory and projection uncertainty has been a significant source of past sea level budget uncertainty and remains a dominant uncertainty until mid-century. Emission scenario becomes the largest source of glacier change uncertainty by 2100 just as the relative importance of glacier loss is projected to decrease (Section 9.5.1).

New high-resolution climate models show that SST, overturning circulation, ocean heat content change and sea-ice cover are considerably improved in most models when compared to the coarser resolution models. Change in the Southern Ocean and adjacent shelves (Section 9.2.3.2) is intimately linked to the future of the Antarctic ice sheet (Section 9.4.2.3), and projection of the Southern Ocean depends on both oceanic and atmospheric drivers affecting heat (and carbon) uptake and sea ice. However, resolution remains a factor, as most CMIP6 models are far from resolutions that directly represent coastal and regional shallow-water

ACCEPTED VERSION SUBJECT TO FINAL EDITING

processes such as those beneath Antarctic ice shelves, in Greenland fjords and the eddying convection found by OSNAP.

Processes that change on long timescales—particularly AMOC, ocean heat content, and ice sheets—require additional projections beyond the CMIP scenarios to explore longer term commitment, post-forcing recovery measured in centuries rather than years or decades, and potential tipping points and thresholds. There were only a few new studies focussed on longer timescales and none based on CMIP6 models.

Frequently Asked Questions

FAQ 9.1: Can continued melting of the Greenland and Antarctic ice sheets be reversed? How long would it take for them to grow back?

Evidence from the distant past shows that some parts of the Earth system might take hundreds to thousands of years to fully adjust to changes in climate. This means that some of the consequences of human-induced climate change will continue for a very long time, even if atmospheric heat-trapping gas levels and global temperatures are stabilized or reduced in the future. This is especially true for the Greenland and Antarctic ice sheets, which grow much more slowly than they retreat. If the current melting of these ice sheets continues for long enough it becomes effectively irreversible on human timescales, as does the sea level rise caused by that melting.

Humans are changing the climate and there are mechanisms that amplify the warming in the polar regions (Arctic and Antarctic). The Arctic is already warming faster than anywhere else (see FAQ 4.3). This is significant because these colder high latitudes are home to our two remaining ice sheets: in Antarctica and Greenland. Ice sheets are huge reservoirs of frozen freshwater, built up by tens of thousands of years of snowfall. If they were to completely melt, the water released would raise global sea level by about 65 m. Understanding how these ice sheets are affected by warming of nearby ocean and atmosphere is therefore critically important. The Greenland and Antarctic ice sheets are already slowly responding to recent changes in climate, but it takes a long time for these huge masses of ice to adjust to changes in global temperature. That means that the full effects of a warming climate may take hundreds or thousands of years to play out. An important question is whether these changes can eventually be reversed, once levels of greenhouse gases in the atmosphere are stabilized or reduced by humans and natural processes. Records from the past can help us answer this question.

For at least the last 800,000 years, the Earth has followed cycles of gradual cooling followed by rapid warming caused by natural processes. During cooling phases, more and more ocean water is gradually deposited as snowfall, causing ice sheets to grow and sea level to slowly decrease. During warming phases, the ice sheets melt more quickly, resulting in more rapid rises in sea level (FAQ 9.1, Figure 1). Ice sheets build up very slowly because growth relies on the steady accumulation of falling snow that eventually compacts into ice. As the climate cools, areas that can accumulate snow expand, reflecting back more sunlight that otherwise would keep the Earth warmer. This means that once started, glacial climates develop rapidly. However, as the climate cools, the amount of moisture that the air can hold tends to decrease. As a result, even though glaciations begin quite quickly, it takes tens of thousands of years for ice sheets to grow to a point where they are in balance with the colder climate.

Ice sheets retreat more quickly than they grow because of processes that, once triggered, drive self-reinforcing ice loss. For ice sheets that are mostly resting on bedrock *above* sea level – like the Greenland ice sheet – the main self-reinforcing loop that affects them is the 'elevation–mass balance feedback' (FAQ 9.1, Figure 1, right). In this situation, the altitude of the ice sheet surface decreases as it melts, exposing the sheet to warmer air. The lowered surface then melts even more, lowering it faster still, until eventually the whole ice sheet disappears. In places where the ice sheet rests instead on bedrock that is *below* sea level and which also deepens inland, including many parts of the Antarctic ice sheet, an important process called 'marine ice-sheet instability' is thought to drive rapid retreat (FAQ 9.1, Figure 1, left). This happens when the part of the ice sheet that is surrounded by sea water melts. That leads to additional thinning, which in turn accelerates the motion of the glaciers that feed into these areas. As the ice sheet flows more quickly into the ocean, more melting takes place, leading to more thinning and even faster flow that brings ever-more glacier ice into the ocean, ultimately driving rapid deglaciation of whole ice-sheet drainage basins.

These (and other) self-reinforcing processes explain why relatively small increases in temperature in the past led to very substantial sea level rise over centuries to millennia, compared to the many tens of thousands of years it takes to grow the ice sheets that lowered the sea level in the first place. These insights from the past imply that if human-induced changes to the Greenland and Antarctic ice sheets continue for the rest of this century, it will take thousands of years to reverse that melting, even if global air temperatures decrease

ACCEPTED VERSION SUBJECT TO FINAL EDITING

within this or the next century. In this sense, these changes are therefore irreversible, since the ice sheets would take much longer to regrow than the decades or centuries for which modern society is able to plan.

SUBJECT TO FINAL EDITING

FAQ 9.2: How much will sea level rise in the next few decades?

As of 2018, global average sea level was about 15–25 cm higher than in 1900 and 7–15 cm higher than in 1971. Sea level will continue to rise by an additional 10–25 cm by 2050. The major reasons for this ongoing rise in sea level are the thermal expansion of seawater as its temperature increases and the melting of glaciers and ice sheets. Local sea level changes can be larger or smaller than the global average, with the smallest changes in formerly glaciated areas and the largest changes in low-lying river delta regions.

Across the globe, sea level is rising, and the rate of increase has accelerated. Sea level increased by about 4 mm per year from 2006 to 2018, which was more than double the average rate over the 20th century. Rise during the early 1900s was due to natural factors, such as glaciers catching up to warming that occurred in the Northern Hemisphere during the 1800s. However, since at least 1970, human activities have been the dominant cause of global average sea level rise, and they will continue to be for centuries into the future.

Sea level rises either through warming of ocean waters or the addition of water from melting ice and bodies of water on land. Expansion due to warming caused about 50% of the rise observed from 1971 to 2018. Melting glaciers contributed about 22% over the same period. Melting of the two large ice sheets in Greenland and Antarctica has contributed about 13% and 7%, respectively, during 1971-2018, but melting has accelerated in the recent decades, increasing their contribution to 22% and 14% since 2016. Another source is changes in land water storage: reservoirs and aquifers on land have reduced, which contributed about a 8% increase in sea level.

By 2050, sea level is expected to rise an additional 10–25 cm whether or not greenhouse gas emissions are reduced (FAQ 9.2, Figure 1). Beyond 2050, the amount by which sea level will rise is more uncertain. The accumulated total emissions of greenhouse gases over the upcoming decades will play a big role beyond 2050, especially in determining where sea level rise and ice sheet changes eventually level off.

Even if net zero emissions are reached, sea level rise will continue because the deep ocean will continue to warm and ice sheets will take time to catch up to the warming caused by past and present emissions: ocean and ice sheets are slow to respond to environmental changes (see FAQ 5.3). Some projections under low emissions show sea level rise continuing as net zero is approached at a rate comparable to today (3–8 mm per year by 2100 versus 3–4 mm per year in 2015), while others show substantial acceleration to more than five times the present rate by 2100, especially if emissions continue to be high and processes that accelerate retreat of the Antarctic Ice Sheet occur widely (FAQ 9.1).

Sea level rise will increase the frequency and severity of extreme sea level events at coasts (see FAQ 8.2),, such as storm surges, wave inundation and tidal floods: risk can be increased by even small changes in global average sea level. Scientists project that in some regions, extreme sea level events that were recently expected once in 100 years will occur annually at 20-25% of locations by 2050 regardless of emissions, but by 2100 emissions choice will matter: annually at 60% of locations for low emissions, and at 80% of locations under strong emissions.

In many places, local sea level change will be larger or smaller than the global average. From year to year and place to place, changes in ocean circulation and wind can lead to local sea level change. In regions where large ice sheets, such as the Fennoscandian in Eurasia and the Laurentide and Cordilleran in North America, covered the land during the last ice age, the land is still slowly rising up now that the extra weight of the ice sheets is gone. This local recovery is compensating for global sea level rise in these regions and can even lead to local decrease in sea level. In regions just beyond where the former ice sheets reached and the Earth bulged upwards, the land is now falling, and as a result local sea level rise is faster than the global rate. In many regions within low-lying delta regions (such as New Orleans and the Ganges–Brahmaputra delta), the land is rapidly subsiding (sinking) because of human activities such as building dams or groundwater and fossil fuel extraction. Further, when an ice sheet melts it has less gravitational pull on the ocean water nearby. This reduction in gravitational attraction causes sea level to fall close to the (now less-massive) ice sheet while causing sea level to rise farther away. Melt from a polar ice sheet therefore raises sea level most in the opposite hemisphere or in low latitudes – amounting to tens of centimetres difference in

rise between regions by 2100.

FAQ 9.3: Will the Gulf Stream shut down?

The Gulf Stream is part of two circulation patterns in the North Atlantic: the Atlantic Meridional Overturning Circulation (AMOC) and the subtropical gyre. Based on models and theory, scientific studies indicate that, while the AMOC is expected to slow in a warming climate, the Gulf Stream will not change much and would not shut down totally, even if the AMOC did. Most climate models project that the AMOC slows in the later 21st century under most emissions scenarios, with some models showing it slowing even sooner. The Gulf Stream affects the weather and sea level, so if it slows, North America will see higher sea levels and Europe's weather and rate of relative warming will be affected.

The Gulf Stream is the biggest current in the North Atlantic Ocean. It transports about 30 billion kilograms of water per second northward past points on the east coast of North America. It is a warm current, with temperatures 5°C to 15°C warmer than surrounding waters, so it carries warmer water (thermal energy) from its southern origins and releases warmth to the atmosphere and surrounding water.

The Gulf Stream is part of two major circulation patterns, the Atlantic Meridional Overturning Circulation (AMOC) and the North Atlantic Subtropical Gyre (FAQ 9.3, Figure 1). The rotation of the Earth causes the big currents in both circulations to stay on the western side of their basin, which in the Atlantic means the circulations combine to form the Gulf Stream. Other large currents contribute to gyres, such as the Kuroshio in the North Pacific and the East Australian Current in the South Pacific, but the Gulf Stream is special in its dual role. There is no comparable deep overturning circulation in the North Pacific to the AMOC, so the Kuroshio plays only one role as part of a gyre.

The gyres circulate surface waters and result primarily from winds driving the circulation. These winds are not expected to change much and so neither will the gyres, which means the gyre portion of the Gulf Stream and the Kuroshio will continue to transport thermal energy poleward from the equator much as they do now. The gyre contribution to the Gulf Stream is 2 to 10 times larger than the AMOC contribution.

The Gulf Stream's role in the AMOC is supplying surface source water that cools, becomes denser and sinks to form cold, deep waters that travel back equatorward, spilling over features on the ocean floor and mixing with other deep Atlantic waters to form a southward current at a depth of about 1500 metres beneath the Gulf Stream. This overturning flow is the AMOC, with the Gulf Stream in the upper kilometre flowing northward and the colder deep water flowing southward.

The AMOC is expected to slow over the coming centuries. One reason why is freshening of the ocean waters: by meltwater from Greenland, changing Arctic sea ice, and increased precipitation over warmer northern seas. An array of moorings across the Atlantic has been monitoring the AMOC since 2004, with recently expanded capabilities. The monitoring of the AMOC has not been long enough for a trend to emerge from variability and detect long-term changes that may be underway (see FAQ 1.2). Other indirect signs may indicate slowing overturning – for example, slower warming where the Gulf Stream's surface waters sink. Climate models show that this 'cold spot' of slower-than-average warming occurs as the AMOC weakens, and they project that this will continue. Paleoclimate evidence indicates AMOC changed significantly in the past, especially during transitions from colder climates to warmer ones, but indicate it has been stable for 8000 years.

What happens if the AMOC slows in a warming world? The atmosphere adjusts somewhat, compensating partly for the decreases in heat carried by AMOC by carrying more heat. But the 'cold spot' makes parts of Europe warm more slowly. Models indicate that weather patterns in Greenland and around the Atlantic will be affected, with reduced precipitation in the mid-latitudes, changing strong precipitation patterns in the tropics and Europe, and stronger storms in the North Atlantic storm track. The slowing of this current combined with the rotation of the Earth means that sea level along North America rises as the AMOC contribution to the Gulf Stream slows.

The North Atlantic is not the only site of sensitive meridional overturning. Around Antarctica, the world's densest seawater is formed by freezing into sea ice, leaving behind salty, cold water that sinks to the bottom

and spreads northward. Recent studies show that melting of the Antarctic Ice Sheet and changing winds over the Southern Ocean can affect this southern meridional overturning, affecting regional weather.

Figure 9.2: Components of ocean, cryosphere and sea level assessed in this chapter. (a) Schematic of processes (mCDW=modified Circumpolar Deep Water, GIA=Glacial Isostatic Adjustment). White arrows indicate ocean circulation. Pinning points indicate where the grounding line is most stable and ice sheet retreat will slow. (b) Geographic distribution of ocean and cryosphere components (numbers indicate (RGI Consortium, 2017) glacierized regions, see Figures 9.20 and 9.21 for labels). Sea ice shaded to indicate the annual mean concentration. Green ocean colours indicate larger surface current speed. Figure 9.3: Sea Surface Temperature (SST) and its changes with time. (a) Time series of global mean SST anomaly relative to 1950-1980 climatology. Shown are observational reanalyses (HadISST) and multi-model means from the CMIP historical, CMIP projections, and HighResMIP experiment. (b) Map of observed SST (1995-2014 climatology HadISST), (e) bias of CMIP and (h) bias of HighResMIP (bottom left) over 1995-2014. Also shown are 1950-2014 c) historical SST changes from observations, (f) CMIP and (i) HighResMIP, and (d) 2005-2100 SST change rate, (g) 2005-2050 change rate for SSP5-8.5 for the CMIP ensemble, and (j) 2005-2050 change rate for SSP5-8.5 for the HighResMIP ensemble. No overlay indicates regions with high model agreement, where ≥80% of models agree on sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

Figure 9.4: Global maps of observed mean fluxes (a, d, g), the observed trends in these fluxes (b, e, h) and the projected rate of change in these fluxes from SSP5-8.5 (c, f, i). Shown are the freshwater flux (a, b, c), net heat flux (d, e, f), and momentum flux or wind stress magnitude (g, h, i), with positive numbers indicating ocean freshening, warming, and accelerating respectively. The means and observed trends are calculated between 1995-2014 (freshwater and wind stress) or 2001-2014 (heat) and the SSP5-8.5 projected rates are between 1995-2100 using 20-year averages at each end of the time period. Observations show objective interpolation from CERES EBAF v4 (Kato et al., 2018), OAFlux-HR (Yu, 2019), and GPCP (Adler et al., 2003) of fluxes and flux trends. (b, e, h) Observed trends with no overlay indicates regions where the trends are significant at $p = 0.34$ level. Crosses indicate regions where trends are not significant. For (c, f, i) projections, no overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

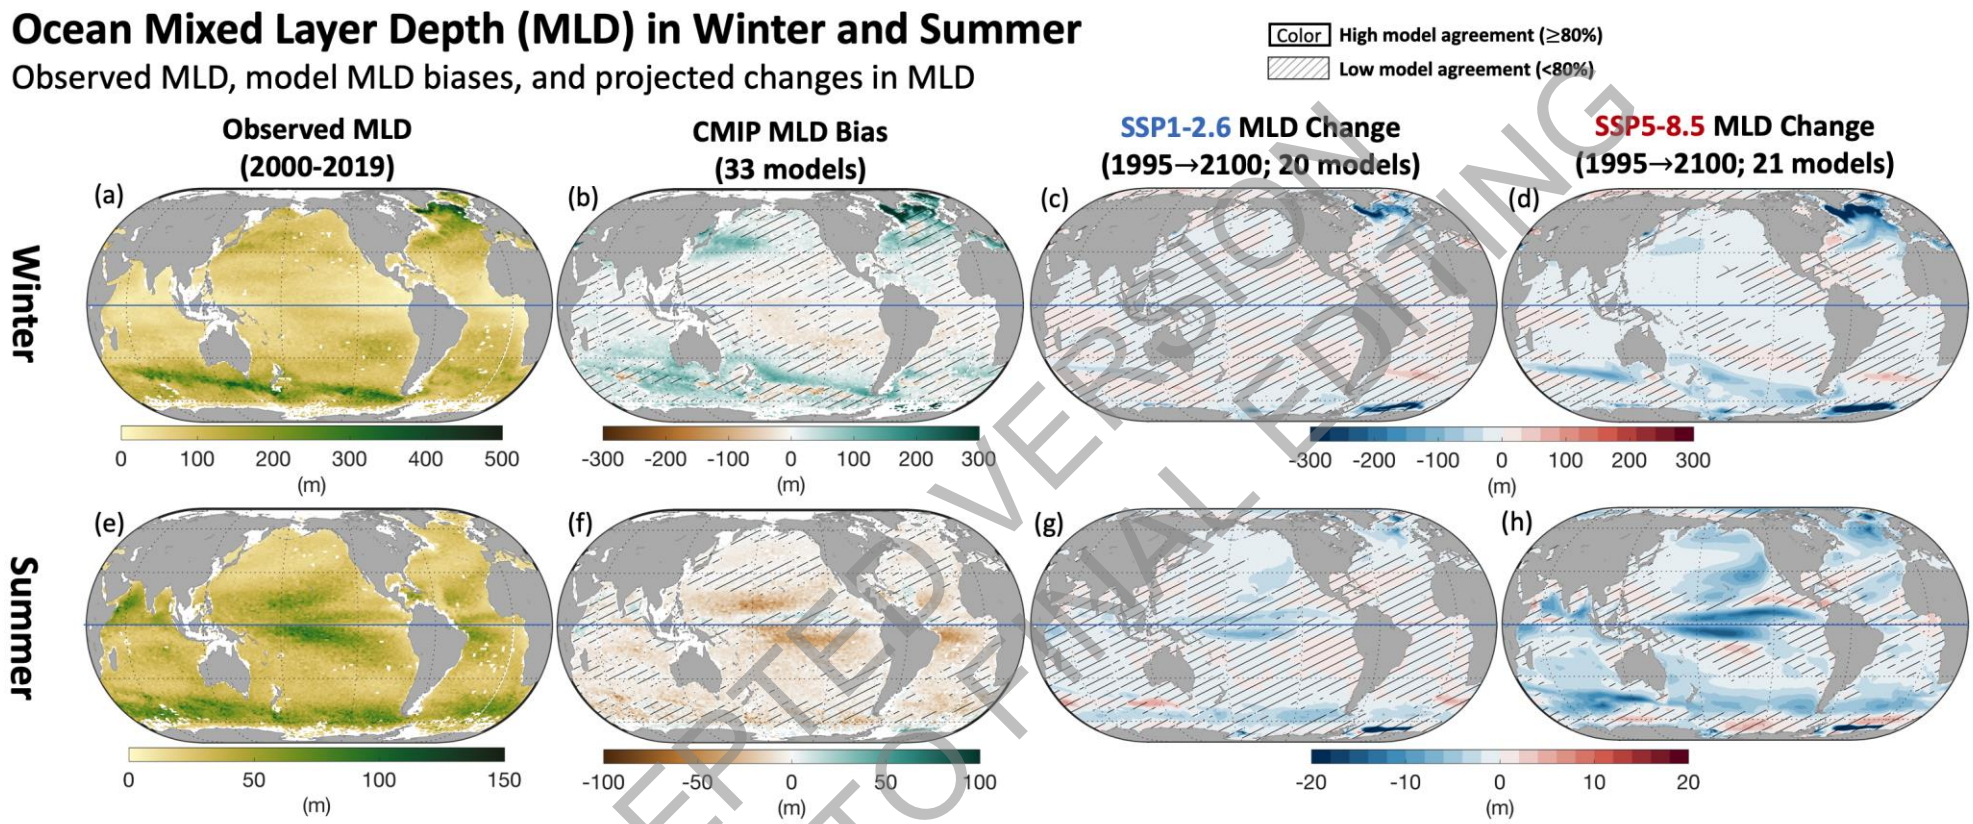

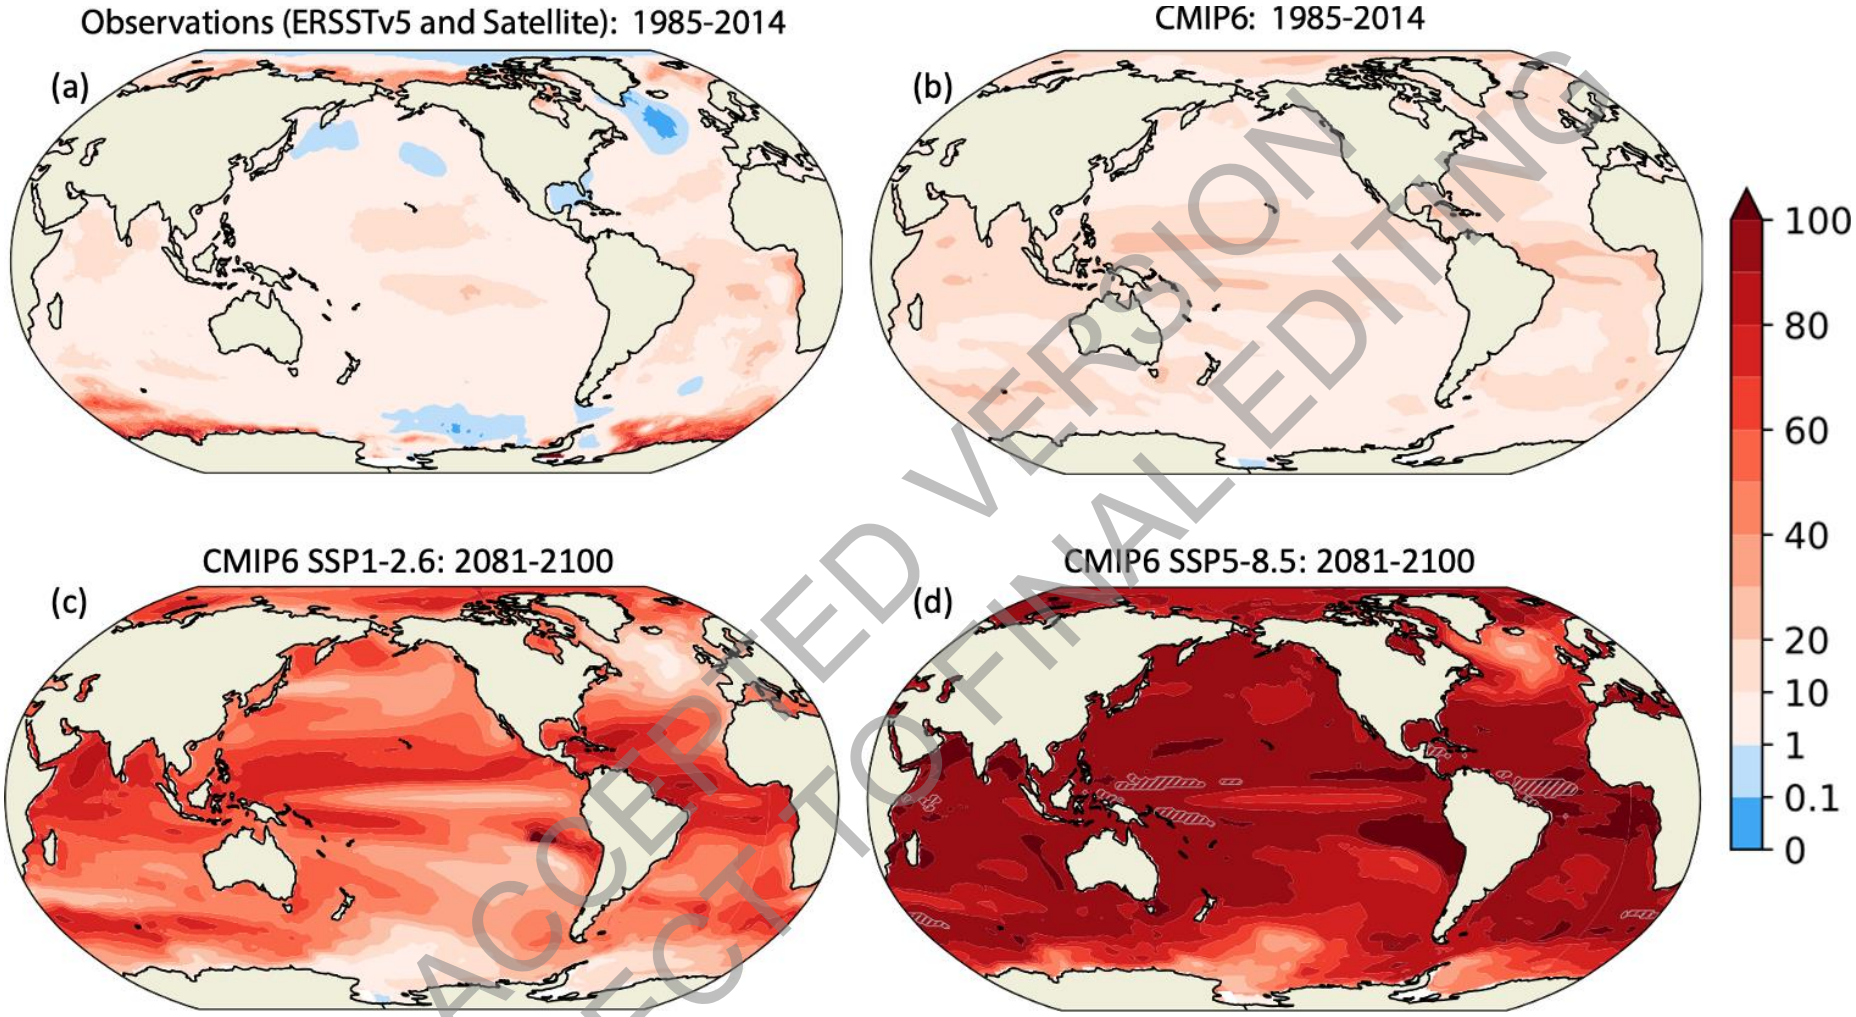

Figure 9.5: **Mixed layer depth in (a-d) winter and (e-h) summer.** (a, e) Observed climatological mean mixed layer depth (based on density threshold) from the Argo Mixed Layer Depth (Holte et al., 2017) **from** observations 2000-2019. (b, f) Bias between the observation-based estimate (2000-2019) and the 1995-2014 CMIP6 climatological mean mixed layer depth. (c, d, g, h) Projected MLD change from 1995-2014 to 2081-2100 under (c, g) SSP1-2.6 and (d, h) SSP5-8.5 scenarios. The (a, b, c, d) Winter row shows DJF in the Northern Hemisphere and JJA in the Southern Hemisphere, and the (e, f, g, h) Summer row shows JJA in the Northern Hemisphere and DJF in the Southern Hemisphere. The mixed layer depth is the depth where the potential density is 0.03 kg m^{-3} denser than at 10m. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

Box 9.2, Figure 1: Observed and simulated regional probability ratio of marine heatwaves (MHWs) for the 1985-2014 period and for the end of the 21st century under two different greenhouse gas emissions scenarios. The probability ratio is the proportion by which the number of MHW days per year has increased relative to preindustrial times. A MHW is defined as a deviation beyond the daily 99th percentile (11-day window) in the deseasonalized sea surface temperature. (a) The MHW probability ratio from satellite observations (NOAA OISST V2.1; Huang et al. 2020) during 1985-2014. The mean warming pattern (difference in ERSST5

ACCEPTED VERSION SUBJECT TO FINAL EDITING

(Huang et al. 2017) sea surface temperature between the 1985-2014 and 1854-1900 periods) has been added to the satellite observations to calculate the probability ratio. (b-d) CMIP6 simulated multi-model mean probability ratio of the (b) 1985-2014 period, and 2081-2100 period in the (c) SSP1 2.6 and (d) SSP5 8.5 scenarios. The areas with grey diagonal lines in (d) indicate permanent MHWs (> 360 heatwave days per year). These 14 CMIP6 models are included in the analysis: ACCESS-CM2, CESM2, CESM2-WACCM, CMCCCM2-SR5, CNRM-CM6-1, CNRM-ESM2-1, CanESM5, EC-Earth3, IPSL-CM6A-LR, MIROC6, MRI-ESM2-0, NESM3, NorESM2-LM, NorESM2-MM. Figure 9.6: Ocean heat content (OHC) and its changes with time. (a) Time series of global ocean heat content anomaly relative to a 2005-2014 climatology in the upper 2000m of the ocean. Shown are observations (Ishii et al., 2017; Baggenstos et al., 2019; Shackleton et al., 2020), model-observation hybrids (Cheng et al., 2019; Zanna et al., 2019), and multi-model means from the CMIP6 historical (29 models) and SSP scenarios (label subscripts indicate number of models per SSP). (b-g) Maps of Ocean Heat Content across different time periods, in different layers, and from different data sets/experiments. Maps show the CMIP6 ensemble bias and observed (Ishii et al., 2017) trends of OHC for (b, c) 0-700m for the period 1971-2014, and (e, f) 0-2000m for the period 2005-2017. CMIP6 ensemble mean maps show projected rate of change 2015-2100 for (d) SSP5-8.5 and (g) SSP1-2.6 scenarios. Also shown are the projected change in 0-700m OHC for (d) SSP1-2.6 and (g) SSP5-8.5 in the CMIP6 ensembles, for the period 2091-2100 versus 2005-2014. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1for more information). Figure 9.7: Meridional-depth profiles of zonal-mean potential temperature in the ocean and its rate of change in the upper 2000m of the Global, Pacific, Atlantic, and Indian Oceans. Shown are (a, e, i, m) observed temperature (Argo climatology 2005-2014), (b, f, j, n) bias of the CMIP6 ensemble over this period, and future changes under (c, g, k, o) SSP1-2.6 and (d, h, l, p) SSP5-8.5. No overlay indicates regions with high model agreement, where ≥80% of models agree on the sign of change; diagonal lines indicate regions with low model agreement, where <80% of models agree on the sign of change (see Cross-Chapter Box Atlas.1 for more information). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

Figure 9.10: AMOC strength in simulations and sensitivity to resolution and forcing. (Top left) AMOC magnitude in PMIP experiments. (Top right) Time series of AMOC from CMIP5 and CMIP6 based on (Menary et al., 2020). (Bottom left) Percent change in AMOC strength per year at different resolutions over the 1950-2050 period with colours for model families (Roberts et al., 2020). (Bottom right) A compilation (Jackson and Wood, 2018) of percentage changes in the simulated AMOC after applying an additional freshwater flux in the subpolar North Atlantic at the surface for a limited time (de Vries and Weber, 2005; Stouffer et al., 2006; Yin and Stouffer, 2007; Jackson, 2013; Liu and Liu, 2013; Jackson and Wood, 2018; Haskins et al., 2019). Symbols indicate whether the AMOC recovers within 200 years (circles), is starting to recover (upwards arrow) or does not recover within 200 years (downwards arrow). Symbol size indicates rate of freshwater input. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

Figure 9.21: Global and regional glacier mass evolution between 1901 and 2100 relative to glacier mass in 2015. Reconstructed glacier mass change through the 20th century (Marzeion et al., 2015) and observed during 1961-2016 (Zemp et al., 2019). Projected (2015-2100) glacier mass evolution is based on the median of three Representative Concentration Pathways (RCPs) emission scenarios (Marzeion et al., 2020). Uncertainties are in all cases the 90% confidence interval. For a better comparison between regions, the maximum relative mass change was set to 200%, although for three regions, the volume changes between 1901 and 2015 exceeded that value. For the Low Latitude, New Zealand, and High Mountain Asia glaciers, the changes were larger than 1000%, 350%, and 250%, respectively. See Figure 9.2 for the location of each region. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

Figure 9.25: Literature global mean sea level (GMSL) projections (m) for 2050 (left) and 2100 (right) since 1995-2014, for RCP 8.5/SSP5-8.5 (top set), RCP 4.5/SSP2-4.5 (middle set), and RCP 2.6/ SSP1-2.6 (bottom set). Projections are standardised to account for minor differences in time periods. Thick bars span from the 17th-83rd

percentile projections, and thin bars span the 5th-95th percentile projections. The different assessments of ice sheet contributions are indicated by 'MED' (ice sheet projections including only processes in whose quantification there is *medium confidence*), 'MICI' (ice sheet projections which incorporate Marine Ice Cliff Instability), and 'SEJ' (structured expert judgement (SEJ) to assess the central range of the ice-sheet projection distributions). 'Survey' indicates the results of a 2020 survey of sea-level experts on GMSL rise from all sources (Horton et al., 2020). Projection categories incorporating processes in which there is *low confidence* ('MICI' and 'SEJ') are lightly shaded. Dispersion among the different projections represents *deep uncertainty*, which arises as a result of *low agreement* regarding appropriate conceptual models describing ice sheet behaviour and *low agreement* regarding probability distributions used to represent key uncertainties. Individual studies are shown in Tables 9.SM.5, 9.SM.6. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

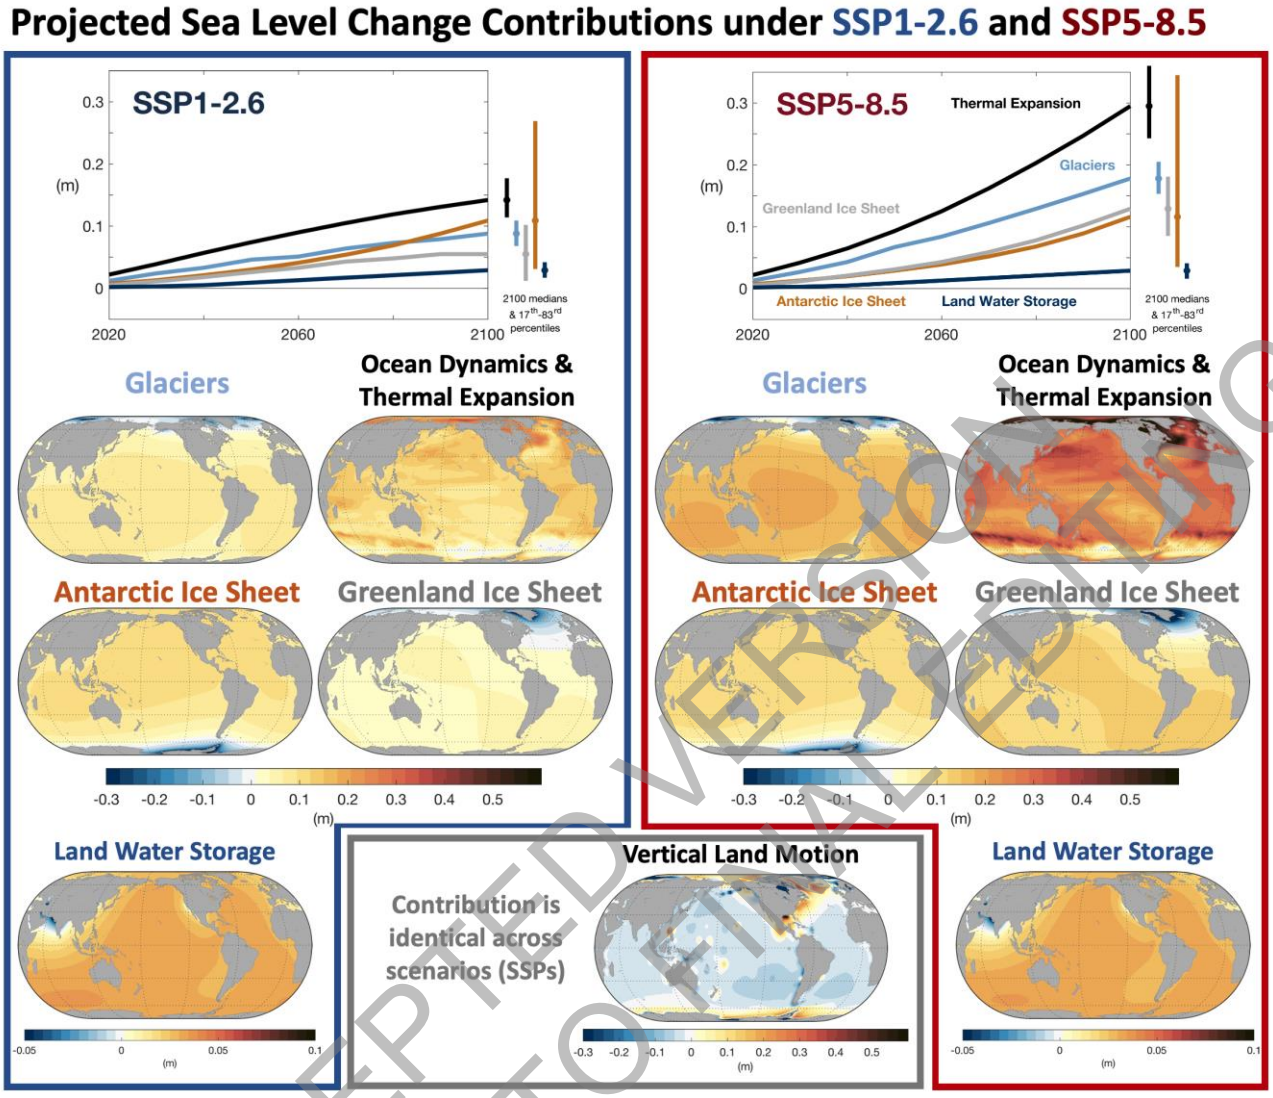

Figure 9.26: Median global mean and regional relative sea-level projections (m) by contribution for the SSP1-2.6 and SSP5-8.5 scenarios. (upper time series) Global mean contributions to sea-level change as a function of time, relative to 1995-2014. (lower maps) Regional projections of the sea-level contributions in 2100 relative to 1995-2014 for SSP5-8.5 and SSP1-2.6. Vertical land motion is common to both SSPs. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

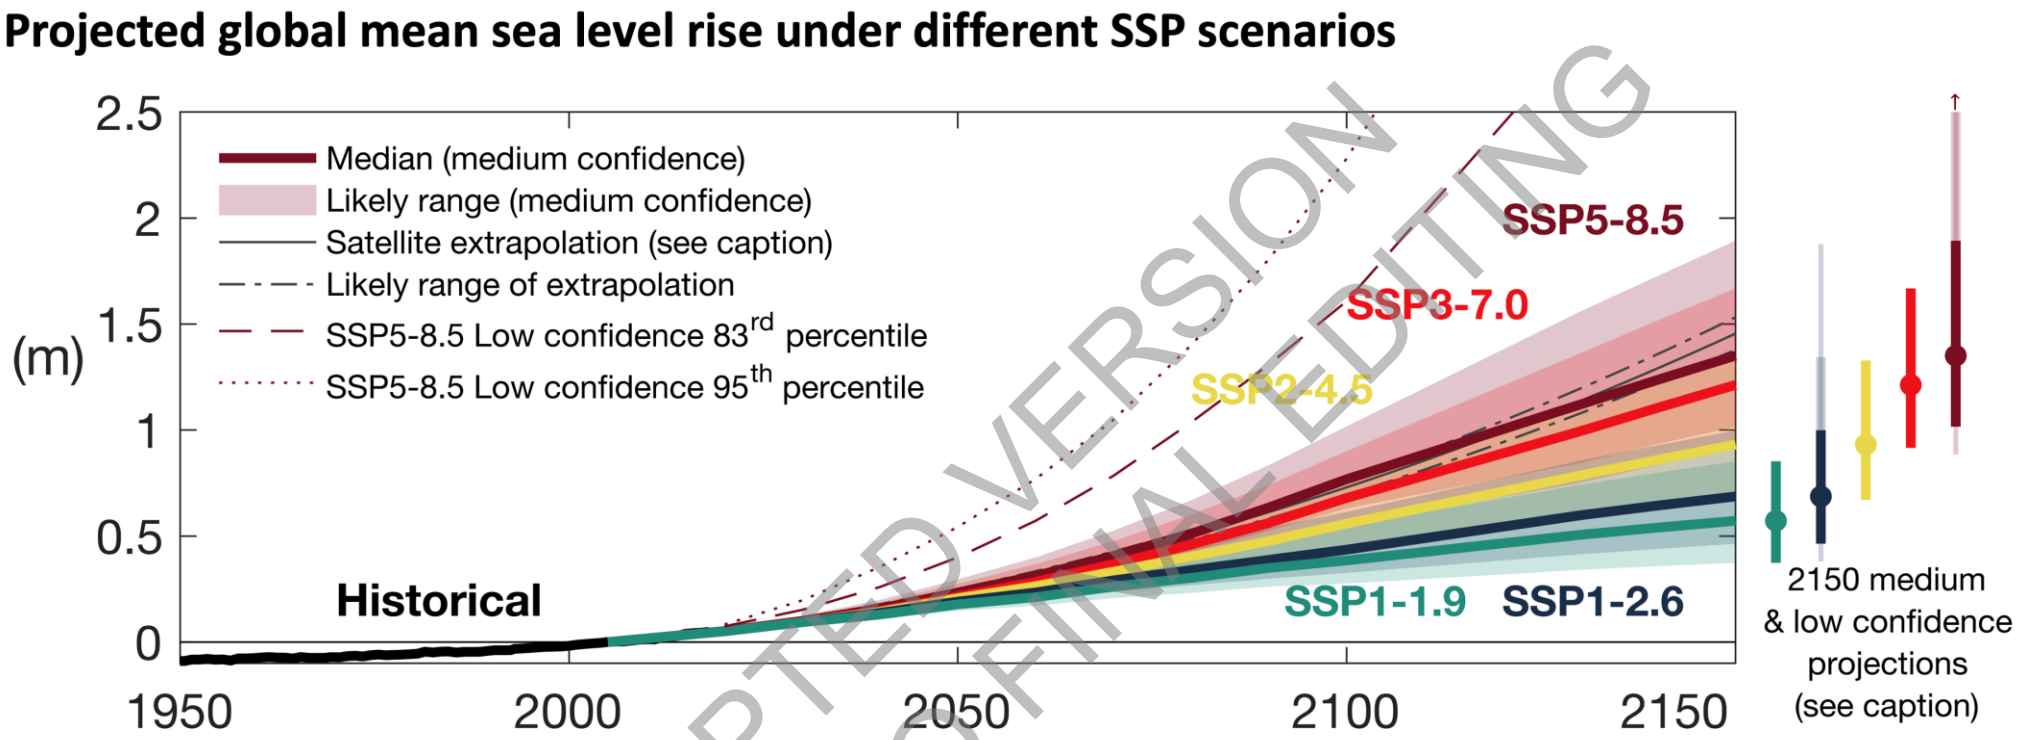

Figure 9.27: Projected global mean sea level rise under different SSP scenarios. *Likely* global mean sea-level change for SSP scenarios resulting from processes in whose projection there is *medium confidence*. Projections and *likely* ranges at 2150 are shown on right. Lightly shaded ranges and thinner lightly shaded ranges on the right show the 17th-83rd and 5th-95th percentile ranges for projections including *low confidence* processes for SSP1-2.6 and SSP5-8.5 only, derived from a p-box including Structured Expert Judgement and Marine Ice Cliff Instability projections. Black lines show historical GMSL change, and thick solid and dash-dotted black lines show the mean and *likely* range extrapolating the 1993-2018 satellite altimeter trend and acceleration. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

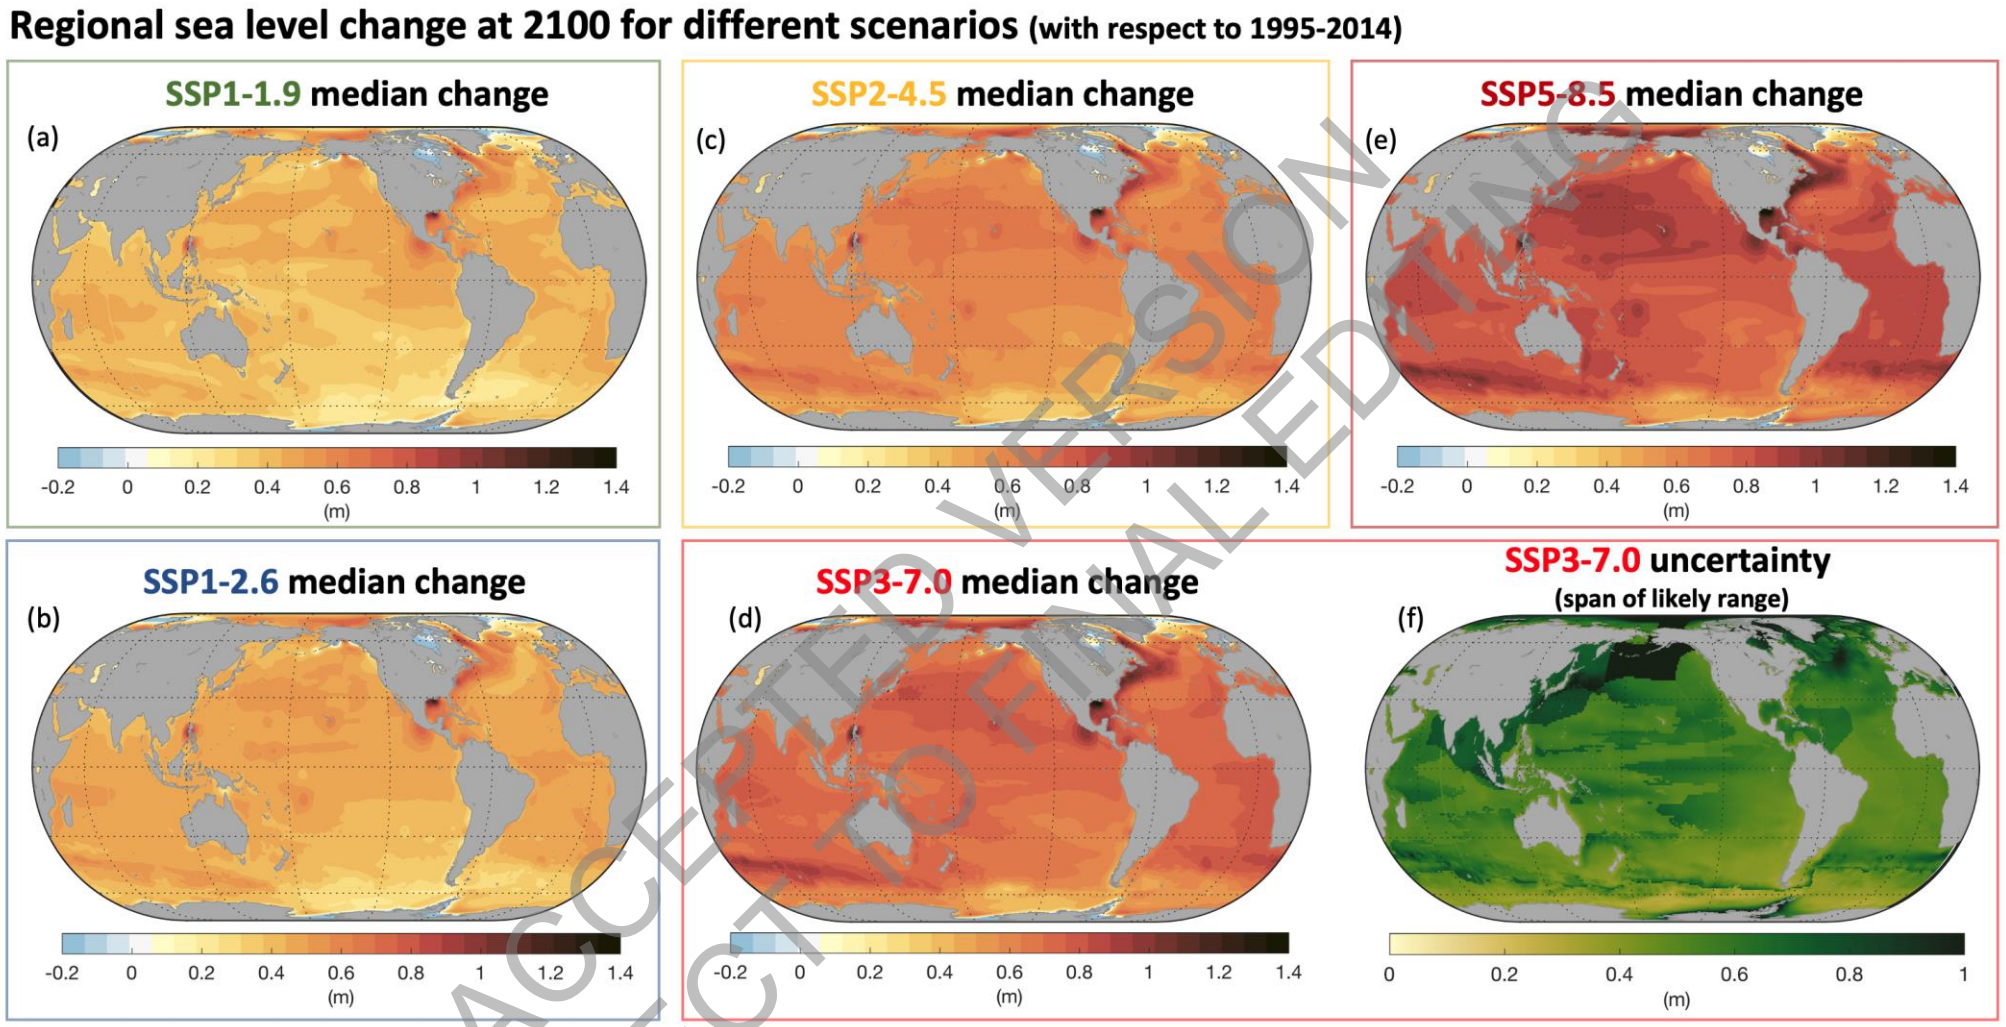

Figure 9.28: Regional sea level change at 2100 for different scenarios (with respect to 1995-2014). Median regional relative sea-level change from 1995 to 2014 up to 2100 for (a) SSP1-1.9, (b) SSP1-2.6, (c) SSP2-4.5, (d) SSP3-7.0, (e) SSP5-8.5, and (f) width of the likely range for SSP3-7.0. The high uncertainty in projections around Alaska and the Aleutian Islands arises from the tectonic contribution to vertical land motion, which varies greatly over short distances in this region. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

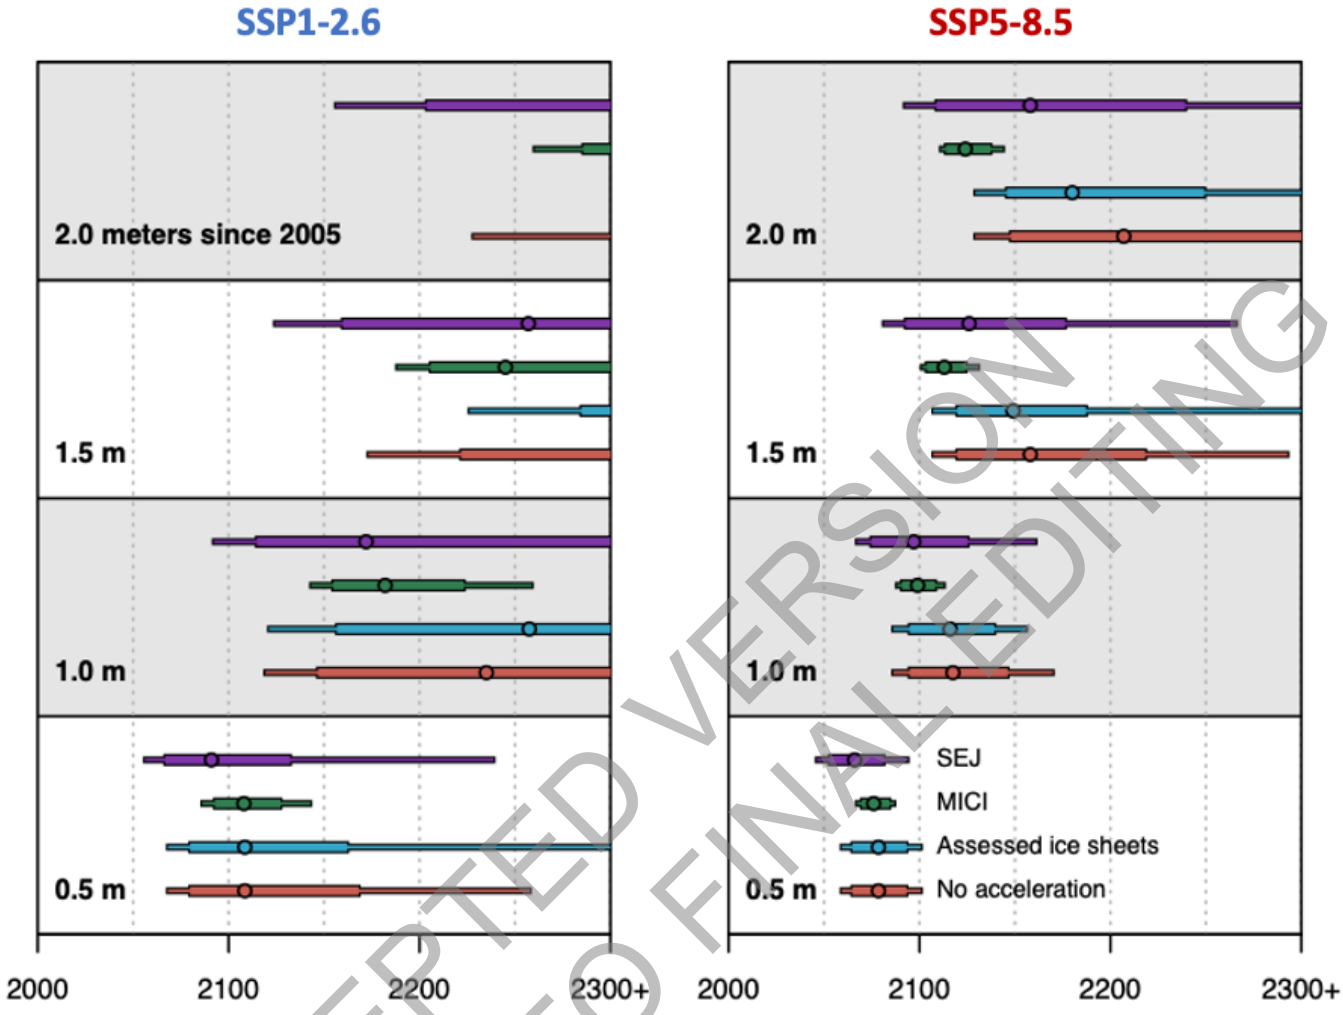

Figure 9.29: Timing of when GMSL thresholds of 0.5, 1.0, 1.5 and 2.0 m are exceeded, based upon four different ice-sheet projection methods informing post-2100 projections. Methods are labelled based on their treatment of ice sheets. "No acceleration" assumes constant rates of mass change after 2100. "Assessed ice sheet" models post-2100 ice sheet losses using a parametric fit (Supplementary Material 9.SM.4) extending to 2300 based on a multimodel assessment of contributions under RCP2.6 and RCP8.5 at 2300. Structured Expert Judgement (SEJ) employs ice-sheet projections from Bamber et al. (2019) Marine Ice Cliff Instability (MICI) combines the parametric fit (Supplementary Material 9.SM3.4) for Greenland with Antarctic projections based on DeConto et al. (2021). Circles/thick bars/thin bars represent the 50th, 17th-83rd, and 5th-95th percentiles of the exceedance timing for the indicated projection method. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

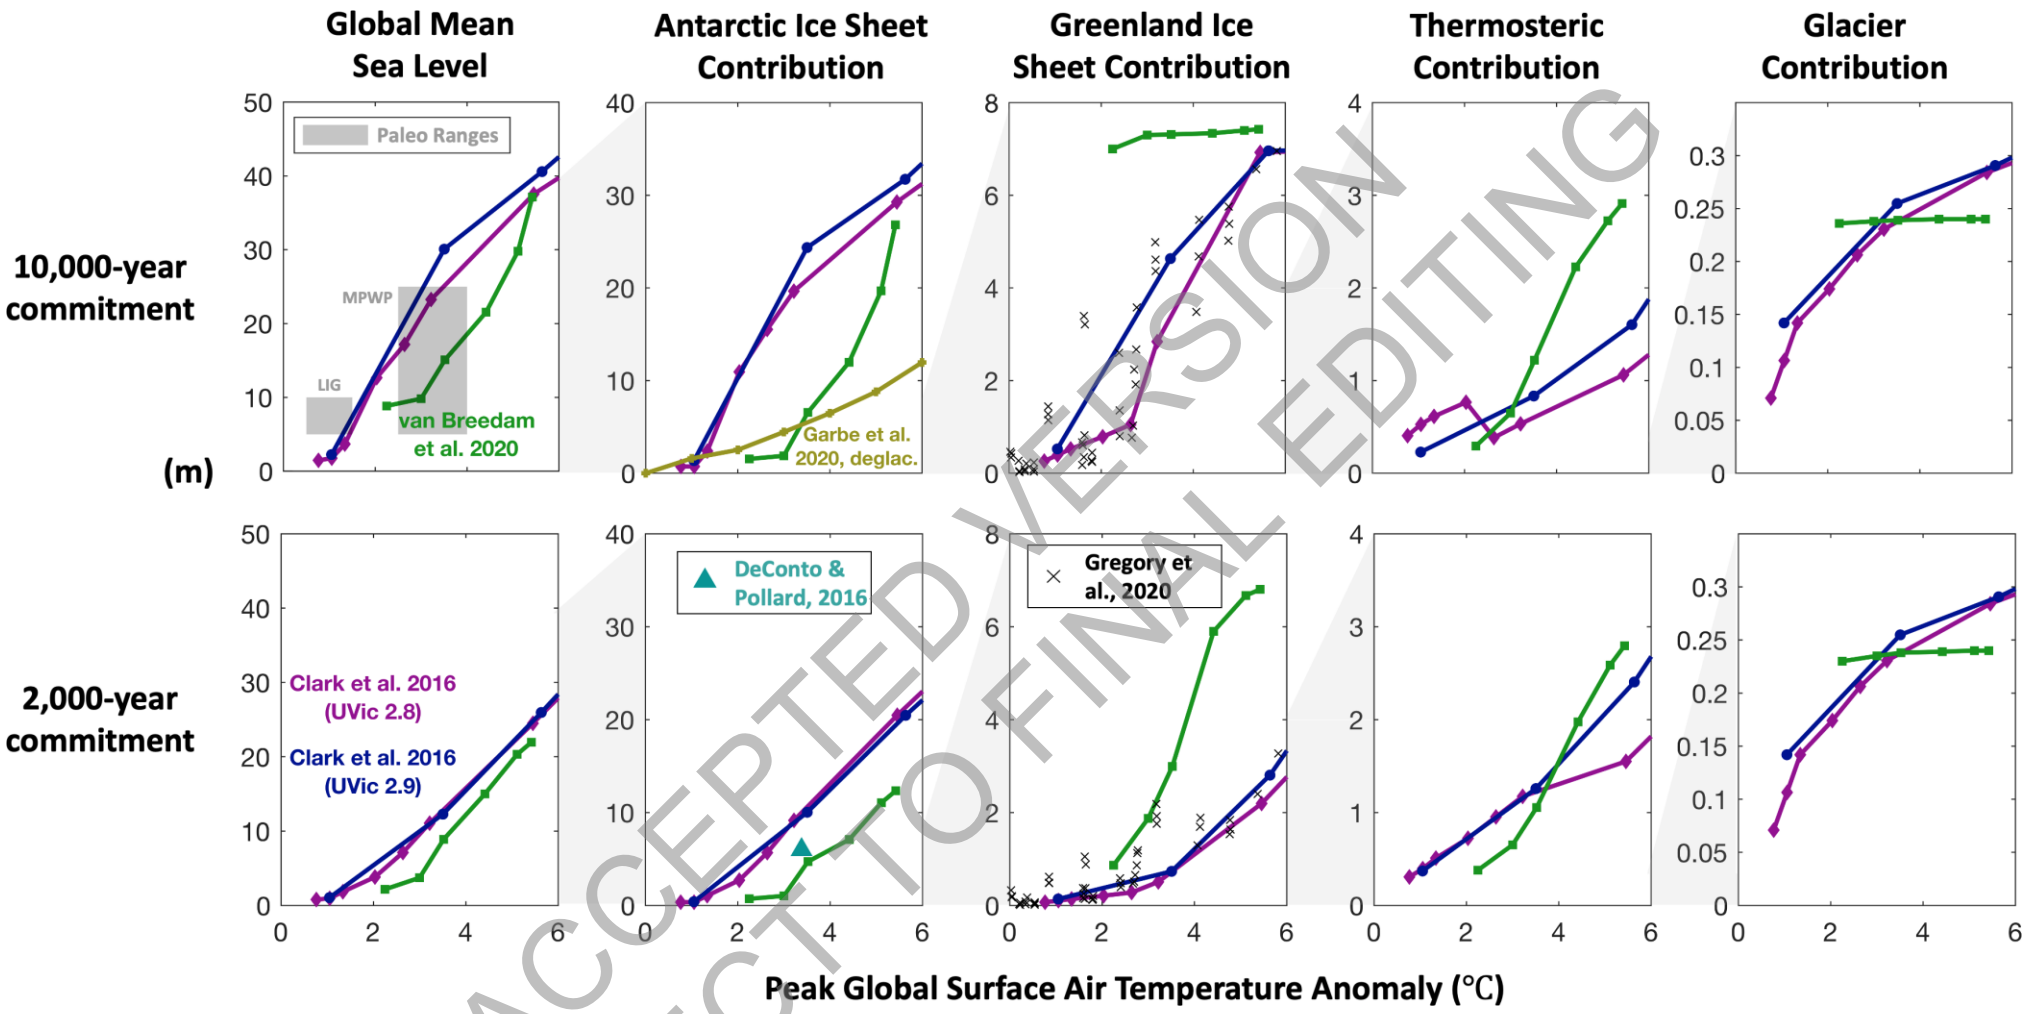

Figure 9.30: Global mean sea-level commitment as a function of peak global surface air temperature. From models (Clark et al., 2016; DeConto and Pollard, 2016; Garbe et al., 2020; Van Breedam et al., 2020) and paleo data on 2000-year (lower row) and 10,000 year (upper row) timescales. Columns indicate different contributors to GMSL rise (from left to right: total GMSL change, Antarctic Ice Sheet, Greenland Ice Sheet, global mean thermosteric sea-level rise, and glaciers). Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

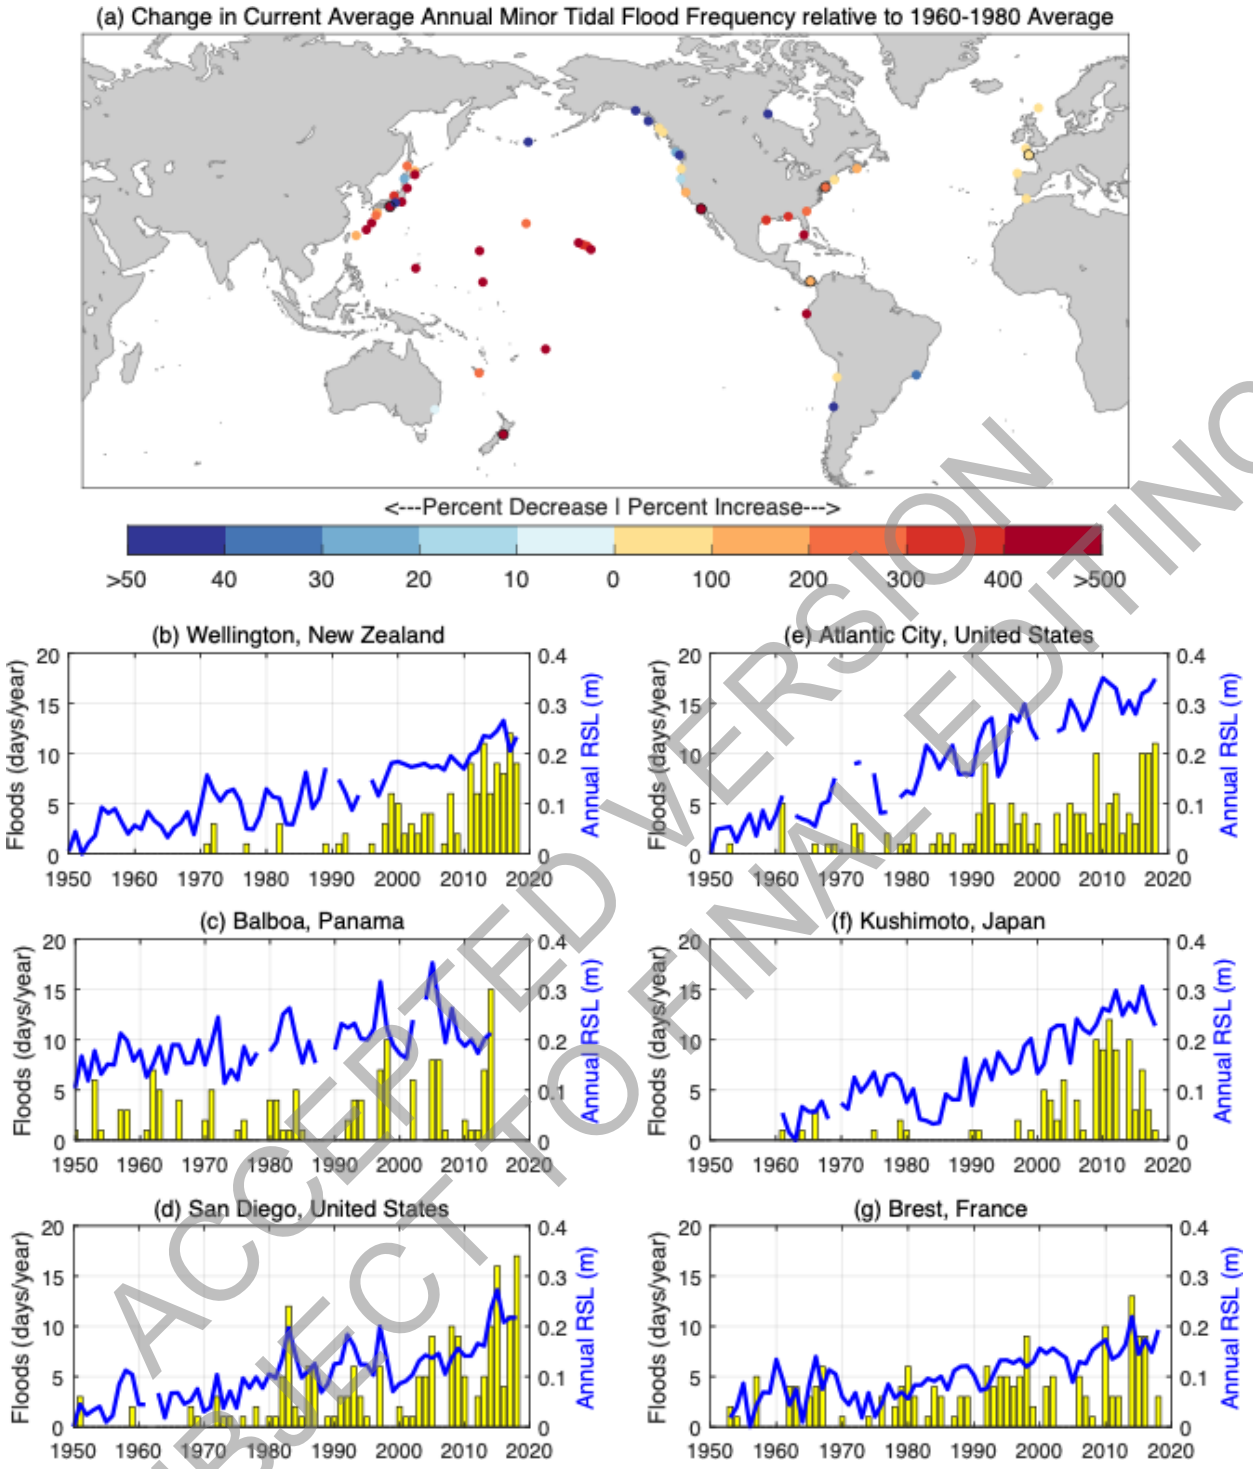

Figure 9.31: Historical occurrences of minor extreme still water levels. Defined as the 99th percentile of daily observed water levels over 1995-2014. (a) Percent change in occurrences over 1995-2014 relative to those over 1960-1980. (b-g) Annual mean sea level (blue) and annual occurrences of extreme still water levels over the 1995-2014 99th percentile daily maximum (yellow) at six selected tide gauge locations. Further details on data sources and processing are available in the chapter data table (Table 9.SM.9).

FAQ 9.1: **Can melting of the ice sheets be reversed?**

Once ice sheets are **destabilised**, it takes them tens of thousands of years to re-grow.
These changes strongly affect **sea level**.

FAQ 9.1, Figure 1: Ice sheets growth and decay (Top) Changes in ice-sheet volume modulate sea level variations. The grey line depicts data from a range of physical environmental sea-level recorders such as coral reefs (see Table 9.SM.5) while the blue line is a smoothed version of it. (Bottom, left) Example of destabilisation mechanism in Antarctica. (Bottom, right) Example of destabilisation mechanism in Greenland.

9.SM.1 Additional ocean information

9.SM.1.1 Details for Figure 9.10

Lower right panel: In all experiments an additional surface freshwater flux (hosing) is applied over the subpolar North Atlantic (regions vary between studies) for a limited time. The total amount of fresh water added is then this flux multiplied by the number of years applied (in Gt). While hosing is applied the AMOC weakens. In some models the AMOC recovers quickly, in other the AMOC hasn't recovered after 200 years, and in some the AMOC is starting to recover after 200 years. These are represented by circles, downward and upward triangles respectively which show the percentage AMOC change after 200 years. Sizes of symbols represent the magnitude of the hosing (from 0.1-1Sv) and colours indicate the different studies these results were taken from (de Vries and Weber, 2005; Stouffer et al., 2006; Yin and Stouffer, 2007; Meehl et al., 2009; Jackson, 2013; Liu and Liu, 2013; Timmermans et al., 2014; Hutchings et al., 2015; Jackson and Wood, 2018; Haskins et al., 2019).

9.SM.4 Additional sea level information

9.SM.4.1 Framework for Assessing Changes To Sea-level (FACTS)

Projections of the probability distributions of global-mean and relative sea-level change are produced using the Framework for Assessing Changes to Sea-level (FACTS), a Python-based modularized framework. Contributors to sea-level change (e.g., ice sheets, ocean dynamics, etc.) are represented as individual modules which are then organized into user-defined projection workflows. The modularity of the framework enables efficient application of the different methodologies described in the chapter. The code for FACTS and its accompanying modules are open source and available through GitHub (https://github.com/radical-collaboration/facts). In the application here, the different drivers are treated as conditionally independent given GSAT.

Ideally, a FACTS module contains a sample-generation method through some sort of statistical or process-based model for the particular component. For example, the module for projecting thermal expansion and dynamic sea-level generates samples from statistical distributions calibrated within the module itself. For modules that use externally-provided ensembles for this report, which include the Emulated ISMIP6 ice sheets simulations, Emulated GlacierMIP glaciers simulations, the LARMIP-2 Antarctic ice sheet simulations, the Marine Ice Cliff Instability Antarctic ice sheet simulations, and the Structure Expert Judgement ice sheets simulations, a bootstrap sampling approach is used. This provides a consistent number

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of samples across all modules within an integrated projection workflow. However, due to this sampling method, the number of samples in the provided ensemble for the module, and the seed value for the random-number generator, small differences may exist between the values of the FACTS produced projections and the values published in the paper for a particular method.

9.SM.4.2 Obtaining Global Mean Thermosteric Sea-Level Rise and Ocean Dynamic Sea-Level Change from CMIP6

We obtained monthly mean values for the CMIP6 variables 'zos' (sea-surface height above geoid), 'zostoga' (global mean thermosteric sea-level change) and 'psl' (air pressure at sea level; required to apply the inverse barometer effect). The data files were extracted from the Earth System Grid Federation (ESGF) database between 22-30 September 2020. Data were obtained for both the historical experiment (1850-2014) and the five core SSPs (2015-2100 and up to 2300 where available) with corresponding variant labels ('ripf' identifier). Additionally, models were required to provide the pre-industrial control output from which the 'zos' and 'zostoga' experiments were initialized, so that 'zos' and 'zostoga' simulations could be corrected for model ocean drift (Gupta et al., 2013; Hobbs et al., 2016b). Thus, the total number of available models used for each emissions scenario depends on the availability of these simulations (and of grid information required to carry out the preprocessing steps detailed in the next paragraph, such as ocean grid cell area 'areacello'). We obtained all available data with an experiment variant with a realization equal to one ('ripf' having 'r'=1). For each model, we use the first of the remaining experiment variants for which most SSP experiments are available, and the first alternative experiment variant for the SSPs for which that variant is not available. For UKESM1-0-LL, the air pressure sea level field yielded an anomalously large inverse barometer effect, so this was model not included.

Then, the timeseries of 'zos' and 'zostoga' were corrected for ocean model drift (Gupta et al., 2013; Hobbs et al., 2016b). This was done by fitting a linear trend to the full pre-industrial control run of each model, and subtracting the resulting linear trend from the historical and scenario runs. Since the drift in 'zostoga' is nearly linear for most CMIP6 models, quadratic or linear drift correction yields little difference compared to the magnitude of projected GTE under the emissions scenarios (Hermans et al., 2021). Additionally, the area-weighted mean of the 'zos' field was removed at each timestep for each model, since 'zos' is defined as the sea-surface height above a time-invariant geoid. Next, 'zos' and 'psl' were bilinearly interpolated to a common regular 1° by 1° grid using the ESMValTool regridding routine (Eyring et al., 2020) . Finally, the inverse barometer effect was derived from sea-level pressure anomalies with respect to the area-weighted ocean mean sea-level pressure (following Stammer and Hüttemann, 2008) and applied to 'zos' in order to obtain ocean dynamic sea-level fields (Gregory et al., 2019). Note that the inverse barometer effect due to sea-ice (e.g., Lyu et al., 2020a) was not applied here.

9.SM.4.3 Global Mean Thermosteric Sea-Level and Ocean Dynamic Sea-Level Projections based on the Two-Layer Emulator

To convert the ocean heat content projections based upon the AR6 assessment of equilibrium climate sensitivity and transient climate response (Appendix 7.A.2) to global mean thermosteric sea-level rise projections, the emulated ocean heat content projections were multiplied with expansion coefficients estimated from CMIP6. A distribution of expansion coefficients was derived by fitting drift-corrected global mean thermosteric sea-level rise (9.SM.4.2) from individual CMIP6 GCMs against total ocean heat content output of a two-layer emulator configured with CMIP6 calibration parameters (Smith et al., 2020b). Both thermosteric sea-level rise and ocean heat content were referenced to their mean values in 1995-2014. The two-layer model was forced with scenario-dependent effective radiative forcing from the RCMIP protocol (Nicholls et al., 2020) for the SSPs. Expansion coefficients were derived through linear regression with a fixed 0-intercept for the period 2015-2100 for all SSPs combined.

The resulting distribution was clipped based on the root mean square error cumulative across scenarios between the GSAT projections of individual CMIP6 models and the GSAT projection of the two-layer

ACCEPTED VERSION SUBJECT TO FINAL EDITING

model calibrated to that model. Only the expansion coefficients of models with an RMSE less than or equal to the 85th percentile of the cumulative distribution function of RMSEs were considered. Thus, the expansion coefficients for CNRM-ESM2-1 and EC-Earth3-Veg were dropped. Expansion coefficients were then randomly drawn from a normal fit to the distribution of remaining expansion coefficients, which has a mean and standard deviation of 0.113 ± 0.013 m/YJ.

To produce ocean dynamic sea-level projections consistent with the global mean thermosteric projections described in this section, we follow the approach of (Kopp et al., 2014). We fit a multivariate t-distribution to the ocean dynamic sea-level terms from CMIP6 (9.SM.4.2), and drawing from this distribution, combine the ocean dynamic sea-level terms with the emulator-based global mean thermosteric projections, accounting for the underlying correlation between global mean thermosteric sea-level rise and ocean dynamic sea-level change in CMIP6. While if the CMIP6 ensemble represented a complete representation of all relevant uncertainties, its 5th-95th percentile range would represent a *very likely* range, it is not a perfect representation, so following practice in the AR5, we treat its 5th-95th percentile range as a *likely range* (i.e., a 17th-83rd percentile range). We therefore scale the standard deviation of the t-distribution of ocean dynamic sea-level change by 1.64, so that ±1 standard deviation of the scaled fitted distribution corresponds to a central 66% *likely range*. To account for identifiable, model-specific problems in specific grid cells (e.g., in inland seas), projections for a grid cell are removed if they have an amplitude in 2099 more than ten times the median local amplitude. In cases where, after removal of extreme outliers, the standard deviation of projections in 2099 is greater than 20 cm, we also remove models that deviate from the mean by more than three standard deviations.

9.SM.4.4 Parametric fit to ISMIP6 Greenland Ice Sheet projections

Since the ISMIP6 emulator does not account for temporal correlation, a polynomial fit to the ISMIP6 results is employed to calculate rates of change. The parametric fit is a cubic fit to temperature and a quadratic fit over time:

$$\frac{\partial s}{\partial t} = \beta_0 + \beta_1 T + \beta_2 T^2 + \beta_3 T^3 + \beta_4 t + \beta_5 t^2$$

Where *s* indicates the sea-level equivalent contribution in mm, *T* is GSAT in °C, and *t* is time in years. For the purposes of fitting this function, *T* and *t* are anomalies to their respective values in year 2015. Fitting is done using maximum a posteriori estimation.

9.SM.4.5 Parametric fit to GlacierMIP2 projections

Since the GlacierMIP2 emulator does not account for temporal correlation and terminates, along with the GlacierMIP2 simulations, in 2100, we employ a power law fit to the GlacierMIP2 simulations (Marzeion et al., 2020), with a functional form similar to that employed by the AR5, to calculate rates of change and extrapolate changes beyond 2100 (up to a maximum potential contribution of 0.32 m). As in the AR5 (Church et al., 2013), the glacier contribution is the integral of $fI(t)^{\rho}$, where $I(t)$ is the time integral of GSAT from 2006 to time t in degrees Celsius year, and the constants f and ρ used for each glacier model are shown in Table 9.SM.4. The spread of the results around this median projection has a coefficient of variation (standard deviation divided by the mean) σ which is determined on a per-model basis. As in the AR5, this variation is incorporated by taking for each Monte Carlo sample a normally distributed random number. This number is multiplied by the time-dependent standard deviation and added to the sample. All models are equally weighted.

9.SM.4.6 Background rates of relative sea-level change

Background rates of RSL change, including glacial-isostatic adjustment as well as other factors contributing to long-term vertical land motion, are estimated from tide-gauge data following the Gaussian-process regression method of Kopp et al. (Kopp et al., 2014). The method was applied to annual-mean tide-gauge data downloaded from the Permanent Service for Mean Sea Level (Holgate et al., 2013) on 18 October 2020. As in Kopp et al. (Kopp et al., 2014), RSL is represented as the sum of three Gaussian processes: (1) a regionally varying, temporally linear process, (2) a globally-uniform process, and (3) a regionally varying, temporally autocorrelated non-linear process. The posterior estimate of the first (temporally linear) process is used as the estimate of the background rate. The analysis is conducted separately for each of 15 regions: Iceland/Svalbard, Scandinavia, Northern Europe, Russia, Mediterranean/Africa, US Pacific, US Atlantic, Gulf of Mexico, Northeastern Canada, Alaska, Latin America, Oceania, Japan, South/East Asia, and Antarctica (see Kopp et al., 2014, for details). Within each region, available tide-gauge data are used together with the GMSL curve of (Dangendorf et al., 2019) (treated as a noisy observation of the second term) to estimate the Gaussian-process model.

9.SM.4.7 Warming Level Scenarios

Because GMSL projections are more strongly related to integrated warming rather than to instantaneous warming, warming-level-based scenarios cannot be defined based on the time-slice method used for atmospheric variables (Cross-Chapter Box 11.1). Instead, consistent with the approaches of (Jackson et al., 2018; Rasmussen et al., 2018), all available SSP-based projections are pooled, then assigned to temperature levels based on the 2081-2100 GSAT anomaly projected by the two-layer energy budget emulator, using a ±0.25°C window around the targeted temperature level. For example, the 2.0°C projections are based on all realizations from all scenarios where 2081-2100 GSAT falls between 1.75°C and 2.25°C. A certain warming level may therefore include a mixture of one or more SSP scenarios.

9.SM.4.8 Analysis of future changes in extreme sea level return frequency

Frequency amplification factors for the 1% average annual-probability of extreme still-water levels are computed by combining the projected regional sea-level change (Section 9.6.3.3) with historical distributions of observed extreme events derived from the Global Extreme Sea Level Analysis 2 (GESLA2;(Woodworth et al., 2016b)) , following the approach of the SROCC and (Frederikse et al., 2020a). GESLA2 stations are included in the analysis when hourly mean data was available for at least 6,000 hours per year (250 days) for at least 20 years. For each station, the annual means were removed before fitting a General Pareto Distribution (GPD) to the hourly mean GESLA2 data using a peak-over-threshold (POT) method with a threshold of 99.7%. The extremes are de-clustered using a minimum of 72 hours between subsequent extremes. The estimated GPD location (the 99.7% threshold), scale and shape parameters are generally in agreement with (Frederikse et al., 2020a). We note that our results are sensitive to the statistical method used (Wahl et al., 2017) and may therefore differ from previous analyses.

Following the SROCC and (Frederikse et al., 2020a), we computed an ensemble of historical return curves for each station using the location parameter in combination with 50,000 random pairs of the shape and scale parameters drawn from the mean estimated shape and scale parameters and their covariance matrices. To compute the future return curves, we use the same scale and shape parameter samples but increase the location parameter at each station by the local projected mean sea-level change, effectively shifting the return curve up. The uncertainty in the local projected mean sea-level change is estimated by drawing 50,000 samples from the projected probability distribution of local mean sea-level change, clipped at its 5^{th} and 95^{th} percentiles. This differs from SROCC, where sea-level change samples were drawn from a normal distribution using the central value and a standard error.

Using the resulting 50,000 future return curves for each station, we calculated the frequency amplification factor of a 1% average annual-probability (i.e., once in 100 years) of extreme still-water level by dividing the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

frequency of that water level in the future return curves by the historical frequency. This resulted in a probability distribution of frequency amplification factors that represents both the uncertainty in projected sea-level change and in the historical distribution of extremes.

Using the POT method, the frequency of extreme events is only defined for water levels above the POT threshold. If the projected sea-level change for a given location is higher than the exceedance of the historical location parameter by the historical 1% annual probability event, the historical 1% annual-probability event would have a return level below the future location parameter. Thus, for the stations where this occurs the frequency amplification factor cannot be fully determined. Therefore, we used the approach of (Buchanan et al., 2016) to describe the return frequency of return heights below the POT threshold. We fit a Gumbel distribution between Mean Higher-High Water (MHHW) and the location parameter, assuming the frequency of exceedance of the MHHW to be 182.6/year. The MHHW was estimated from the GESLA2 data as the long-term mean of 2-daily maxima for each location. Therefore, by construction, the maximum projected frequency amplification factor in our analysis is 18,262.5.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Executive Summary

Although climate change is a global phenomenon, its manifestations and consequences are different in different regions, and therefore climate information on spatial scales ranging from sub-continental to local is used for impact and risk assessments. Chapter 10 assesses the foundations of how regional climate information is distilled from multiple, sometimes contrasting, lines of evidence. Starting from the assessment of global-scale observations in Chapter 2, Chapter 10 assesses the challenges and requirements associated with observations relevant at the regional scale. Chapter 10 also assesses the fitness of modelling tools available for attributing and projecting anthropogenic climate change in a regional context starting from the methodologies assessed in Chapters 3 and 4. Regional climate change is the result of the interplay between regional responses to both natural forcings and human influence (considered in Chapters 2, 5, 6 and 7), responses to large-scale climate phenomena characterizing internal variability (considered in Chapters 1–9), and processes and feedbacks of a regional nature.

Chapter 10 is the first of four chapters that assess regional-scale information in this report. The region-by-region assessment of past and future changes in extremes (Chapter 11), climatic impact-drivers (Chapter 12) and mean climate (Atlas) relies on the sources and methodologies used for constructing regional climate change information assessed in Chapter 10. Building on the assessment of observations and modelling tools of Chapter 10, Chapter 11 assesses the observation and modelling of extremes. Chapter 10 assesses methodologies to attribute multi-decadal regional trends to the interplay between external forcing and internal variability, while Chapter 11 assesses the attribution of extreme events. The assessment of climate services in Chapter 12 builds on the assessment of distillation of regional climate information from multiple lines of evidence in Chapter 10.

Distilling regional climate information from multiple lines of evidence and taking the user context into account will increase the fitness, usefulness and relevance for decision-making and enhances the trust users will have in applying it (*high confidence*). This distillation process can draw upon multiple observational datasets, ensembles of different model types, process understanding, expert judgement and indigenous knowledge. Important elements of distillation include attribution studies, the characterization of possible outcomes associated with internal variability and a comprehensive assessment of observational, model and forcing uncertainties and possible contradictions using different analysis methods. Taking the values of the relevant actors into account when co-producing climate information, and translating this information into the broader user context, improves the usefulness and uptake of this information (*high confidence*). {10.5}

Observations and Models as Sources of Regional Information

The use of multiple sources of observations and tailored diagnostics to evaluate climate model performance increases trust in future projections of regional climate (*high confidence*). The availability of multiple observational records, including reanalyses, that are fit for evaluating the phenomena of interest and account for observational uncertainty, are fundamental for both understanding past regional climate change and assessing climate model performance at regional scales (*high confidence*). Employing tailored, process-oriented and potentially multivariate diagnostics to evaluate whether a climate model realistically simulates relevant aspects of present-day regional climate increases trust in future projections of these aspects (*high confidence*). {10.2.2, 10.3.3}

Currently, scarcity and reduced availability of adequate observations increase the uncertainty of long-term temperature and precipitation estimates (*virtually certain*). Precipitation measurements in mountainous areas, especially of solid precipitation, are strongly affected by gauge location and setup (*very high confidence*). Over data-scarce regions or over complex orography, gridded temperature and precipitation products are strongly affected by interpolation methods. Lack of access to the raw station data used to create gridded products compromises the trustworthiness of these products since the influence of the gridding process on the product cannot be assessed. The use of statistical homogenization methods reduces uncertainties related to long-term warming estimates at regional scales (*virtually certain*) {10.2.2, 10.6.2, 10.6.3, 10.6.4, Box 10.3}.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Regional reanalyses provide surrogates of observed climate variables that are highly relevant in areas with scarce surface observations. Regional reanalyses represent the distributions of precipitation, surface air temperature, and surface wind, including the frequency of extremes, better than global reanalyses (*high confidence*). However, their usefulness is limited by their short length, the typical regional model errors, and the relatively simple data assimilation algorithms. {Section 10.2.1}

Global and regional climate models are important sources of climate information at the regional scale. Global models by themselves provide a useful line of evidence for the construction of regional climate information through the attribution or projection of forced changes or the quantification of the role of the internal variability (*high confidence*). Dynamical downscaling using regional climate models adds value in representing many regional weather and climate phenomena, especially over regions of complex orography or with heterogeneous surface characteristics (*very high confidence*). Increasing climate model resolution improves some aspects of model performance (*high confidence*). Some local-scale phenomena such as land-sea breezes and mountain wind systems can only be realistically represented by simulations at a resolution of the order of 10 km or finer (*high confidence*). Simulations at kilometre-scale resolution add value in particular to the representation of convection, sub-daily precipitation extremes (*high confidence*) and soil-moisture precipitation feedbacks (*medium confidence*). Sensitivity experiments aid the understanding of regional processes and can provide additional user-relevant information. {10.3.3, 10.4, 10.5, 10.6}.

The performance of global and regional climate models and their fitness for future projections depend on their representation of relevant processes, forcings and drivers and on the specific context. Improving global model performance for regional scales is fundamental for increasing their usefulness as regional information sources. It is also key for improving the boundary conditions for dynamical downscaling and the input for statistical approaches, in particular when regional climate change is strongly influenced by large-scale circulation changes. Increasing resolution per se does not solve all performance limitations. Including the relevant forcings (e.g., aerosols, land-use change and stratospheric ozone concentrations) and representing the relevant feedbacks (e.g., snow–albedo, soil-moisture–temperature, soil-moisture–precipitation) in global and regional models is a prerequisite for reproducing historical regional trends and ensuring fitness for future projections (*high confidence*). The sign of projected regional changes of variables such as precipitation and wind speed is in some cases only simulated in a trustworthy manner if relevant regional processes are represented (*medium confidence*). {10.3.3, 10.4.1, 10.4.2, 10.6.2, Cross-Chapter Box 10.2}.

Statistical downscaling, bias adjustment and weather generators are useful approaches for improving the representation of regional climate from dynamical climate models. Statistical downscaling methods with carefully chosen predictors and an appropriate model structure for a given application realistically represent many statistical aspects of present-day daily temperature and precipitation (*high confidence*). Bias adjustment has proven beneficial as an interface between climate model projections and impact modelling in many different contexts (*high confidence*). Weather generators realistically simulate many statistical characteristics of present-day daily temperature and precipitation, such as extreme temperatures and wet- and dry-day transition probabilities (*high confidence*). {10.3.3}

The performance of statistical downscaling, bias adjustment and weather generators in climate change applications depends on the specific model and on the dynamical climate model driving it. Knowledge is still limited about suitable predictors for statistical downscaling of regional climate change, particularly for precipitation. Bias adjustment cannot overcome all consequences of unresolved or strongly misrepresented physical processes, such as large-scale circulation biases or local feedbacks, and may instead introduce other biases and implausible climate change signals (*medium confidence*). Using bias adjustment as a method for statistical downscaling, particularly for coarse-resolution global models, may lead to substantial misrepresentations of regional climate and climate change (*medium confidence*). Instead, dynamical downscaling may resolve relevant local processes prior to bias adjustment, thereby improving the representation of regional changes. The performance of statistical approaches and their fitness for future projections depends on predictors and change factors taken from the driving dynamical models (*high confidence*) {10.3.3, Cross-Chapter Box 10.2}.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Different types of climate model ensembles allow for the assessment of regional climate projection uncertainties, although ensemble spread is not a full measure of the uncertainty (*very high confidence*). Multi-model ensembles enable the assessment of regional climate response uncertainty (*very high confidence*). Discarding models that fundamentally misrepresent processes relevant for a given purpose improves the fitness of multi-model ensembles for generating regional climate information (*high confidence*). At the regional scale, multi-model mean and ensemble spread are not sufficient to characterize low-probability, high-impact changes or situations where different models simulate substantially different or even opposing changes (*high confidence*). In such cases, storylines aid the interpretation of projection uncertainties. Since AR5, the availability of multiple single-model initial-condition large ensembles (SMILEs) allows for a more robust separation of model uncertainty and internal variability in regional-scale projections and provides a more comprehensive spectrum of possible changes associated with internal variability (*high confidence*). {10.3.4}

Interplay between Human Influence and Internal Variability at Regional Scales

Human influence has been a major driver of regional mean temperature change since 1950 in many sub-continental regions of the world (*virtually certain*). Regional-scale detection and attribution studies as well as observed emergence analysis provide robust evidence supporting the dominant contribution of human influence to regional temperature changes over multidecadal periods. {10.4.1; 10.4.3}

While human influence has contributed to multi-decadal mean precipitation changes in several regions, internal variability can delay emergence of the anthropogenic signal in long-term precipitation changes in many land regions (*high confidence*). Multiple attribution approaches, including optimal fingerprinting, grid-point detection, pattern recognition and dynamical adjustment methods, as well as multi-model, single-forcing large ensembles and multi-centennial paleoclimate records, support the contribution of human influence to several regional multi-decadal mean precipitation changes (*high confidence*). At regional scale, internal variability is stronger and uncertainties in observations, models and human influence are all larger than at the global scale, precluding a robust assessment of the relative contributions of greenhouse gases, stratospheric ozone, different aerosol species and land use/land cover changes. Multiple lines of evidence, combining multi-model ensemble global projections with those coming from SMILEs, show that internal variability is largely contributing to the delayed or absent emergence of the anthropogenic signal in long-term regional mean precipitation changes (*high confidence*). {10.4.1, 10.4.2, 10.4.3, 10.6.3, 10.6.4}

Various mechanisms operating at different time scales can modify the amplitude of the regional-scale response of temperature, and both the amplitude and sign of the response of precipitation, to human influence (*high confidence*). These mechanisms include non-linear temperature, precipitation and soil moisture feedbacks, slow and fast responses of sea surface temperature patterns and atmospheric circulation changes to increasing greenhouse gases. {10.4.3}

Urban Climate

Many types of urban parameterizations simulate radiation and energy exchanges in a realistic way (*very high confidence*). For urban climate studies focusing on the interplay between the urban heat island and regional climate change, a simple single-layer parameterization is fit for purpose (*medium confidence*). New networks of monitoring stations in urban areas provide key information to enhance the understanding of urban microclimates and improve urban parameterizations. {Box 10.3}

The difference in observed warming trends between cities and their surroundings can partly be attributed to urbanization (*very high confidence*). Annual-mean daily minimum temperature is more affected by urbanization than annual-mean daily maximum temperature (*very high confidence*). The global annual-mean surface air temperature response to urbanization is, however, negligible (*very high confidence*). {Box 10.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Future urbanization will amplify the projected air temperature change in cities regardless of the characteristics of the background climate, resulting in a warming signal on minimum temperatures that could be as large as the global warming signal (*very high confidence*). A large effect is expected from the combination of future urban development and more frequent occurrence of extreme climatic events, such as heatwaves (*very high confidence*). {Box 10.3}

Distillation of Regional Climate Information

The process of distilling regional climate information from multiple lines of evidence can vary substantially from one case to another. Although methodologies for distillation have been established, the process is in practice conditioned by the sources available, the actors involved and the context, which depend heavily on the regions considered, and framed by the question being addressed. To make the most appropriate decisions and responses to changing climate, it is necessary to consider all physically plausible outcomes from multiple lines of evidence, especially in the case when they are contrasting. {10.5, 10.6, Cross-Chapter Box 10.1, Cross-Chapter Box 10.3}

Confidence in the distilled regional climate information is enhanced when there is agreement across multiple lines of evidence. For example, the apparent contradiction between the observed decrease in Indian monsoon rainfall over the second half of the 20th century and the projected long-term increase is explained by attribution of the trends to different forcings, with aerosols dominating recently and greenhouse gases in the future (*high confidence*). For the Mediterranean region, the agreement between different lines of evidence, such as observations, projections by regional and global models, and understanding of the underlying mechanisms, provides *high confidence* in summer warming that exceeds the global average. {10.5.3, 10.6, 10.6.3, 10.6.4, Cross-Chapter Box 10.3}

The outcome of distilling regional climate information can be limited by inconsistent or contradictory information. Initial observational analyses of the Cape Town drying showed a strong, post-1979 association between increasing greenhouse gases, changes in a key mode of variability (the Southern Annular Mode) and drought in the Cape Town region. However, not all global models show this association, and subsequent analysis extending farther back in time, when human influence was weaker, showed no strong association in observations between the Southern Annular Mode and Cape Town drought. Thus, despite the consistency among global-model future projections, there is *medium confidence* in a projected future drier climate for Cape Town. Likewise, the distillation process results in *low confidence* in the influence of Arctic warming on mid-latitude climate because of contrasting lines of evidence. {10.5.3, 10.6.2, Cross-Chapter Box 10.1, Cross-Chapter Box 10.3}

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.1 Foundations for regional climate change information

10.1.1 Introduction

This chapter assesses the foundations for the distillation of regional climate change information from multiple lines of evidence. The AR5, SR1.5 and SRCCL reports underlined the relevance of assessing regional climate information that is useful and relevant to the decision scale (Box 10.1). To respond to this need, the WGI report of AR6 includes four regional chapters of which this is the first one. Chapter 10 assesses the sources and methodologies used by the Chapters 11, 12 and Atlas to construct regional information. Chapter 10 builds on the assessment of methodologies considered to contruct global climate change information in Chapters 2–4 and on the processes assessed in Chapters 5–9. Additionally, this chapter assesses the methodologies for the co-production of regional climate information, the role of the different actors involved in the process and the relevance of the user context and values.

Regional climate change refers to a change in climate in a given region (Section 10.1.2.1) identified by changes in the mean or higher moments of the probability distribution of a climate variable and persisting for a few decades or longer. It can also refer to a change in temporal properties such as persistence and frequency of occurrence of weather and climate extreme events. Regional climate change may be caused by natural internal processes such as atmospheric internal variability and local climate response to low-frequency modes of climate variability (Technical Annex IV), as well as by changes in external forcings such as modulations of the solar cycle, orbital forcing, volcanic eruptions, and persistent anthropogenic changes in the composition of the atmosphere or in land use and land cover (Cross-Chapter Box 3.2; IPCC, 2018a), in addition to the interactions and feedbacks between them. Process interaction in space is pervasive, which means that small spatial scales have an influence on the larger scales (Palmer, 2013). Depending on the context, a region may refer to a large area such as a monsoon region, but may also be confined to smaller areas such as coastlines, mountain ranges or human settlements like cities. Users (understood as anyone incorporating climate information into their activity) often request climate information for these range of scales since their operating and adaptation decision scales range from the local to the sub-continental level.

Given the many types of regional climates, the broad range of spatial and temporal scales (Section 10.1.2), and the diversity of user needs, a variety of methodologies and approaches have been developed to construct regional climate change information. The sources include global and regional climate model simulations, statistical downscaling and bias adjustment methods. A commonly used source is long-term (end-of century) model projections of regional climate change, as well as near-term (next 10 years) climate predictions (Kushnir et al., 2019; Rössler et al., 2019a). Regional observations, with their associated challenges, are a key source for the regional climate information construction process (Li et al., 2020b). High-quality observations that enable monitoring of the regional aspects of climate are used to adjust inherent model biases and are the basis for assessing model performance. Process understanding and attribution of observed changes to large- and regional-scale anthropogenic and natural drivers and forcings are also important sources.

All these sources are used, when available, to distil regional climate information from multiple lines of evidence (Figure 10.1). The resulting climate information can then be integrated, following a co-production process involving both the user and the producer, into a user context that often is already taken into account when constructing the regional climate information. In fact, the distillation process leading to the climate information can consider the specific context of the question at stake, the values of both the user and the producer, and the challenge of communicating across different communities (Section 10.5).

The chapter (Figure 10.2) starts with an introduction of the concepts used in the distillation of regional climate information (Section 10.1). Section 10.2 addresses the aspects associated with the access to and use of observations, while different modelling approaches are introduced and assessed in Section 10.3. Section 10.3 also addresses the performance of models in simulating relevant climate characteristics as needed to estimate the credibility of future projections. Section 10.4 assesses the interplay between anthropogenic causes and internal variability at regional scales, and its relevance for the attribution of regional climate changes and the emergence of regional climate change signals. Section 10.5 tackles the issue of how regional

ACCEPTED VERSION SUBJECT TO FINAL EDITING

climate information is distilled from different sources taking into account the context and the values of both the producer and the user. Section 10.6 illustrates the distillation approach using three comprehensive examples. Finally, Section 10.7 lists some limitations to the assessment of regional climate information.

10.1.2 Regional Climate Change and the Relevant Spatial and Temporal Scales

The global coupled atmosphere-ocean-land-cryosphere system, including its feedbacks, shows variability over a wide spectrum of spatial and temporal scales (Hurrell et al., 2009). This section discusses concepts and definitions of what can be considered a region, the relevant temporal scales and region-specific aspects of the baselines used.

[START FIGURE 10.3 HERE]

[END FIGURE 10.3 HERE]

10.1.2.1 Spatial scales and definition of regions

Large-scale climate and the associated phenomena have been defined in Chapter 2 (e.g., Cross-Chapter Box 2.2) as ranging from global and hemispheric, to ocean-basin and continental scales. The definition of the regional scale is case specific in the WGI AR6 report. Section 1.4.5 provides definitions of the different regional types adopted by the different Chapters. In this chapter, regional scales are defined as ranging from the size of sub-continental areas (e.g., the Mediterranean basin) to local scales (e.g., coastlines, mountain ranges and cities) without prescribing any formal regional boundaries. These spatial length scales range from a few thousand down to a few kilometres and the relevant driving modes and processes at regional scales are summarized in Figure 10.3. In contrast to Chapters 11, 12 and Atlas, which make a region-by-region assessment of climate change, this chapter does not necessarily restrict itself to the use of the AR6 regions (Sections 1.4.5, Atlas.1.3). Different regional definitions have been used in sections 10.4 and 10.6, selected for their adequacy to illustrate methodological aspects (e.g., for the attribution of long-term regional trends, regions that display such trends have been selected). Typological regions (Sections 1.4.5, Atlas.1.3) are used in Box 10.3 and Cross-Chapter Box 10.4.

10.1.2.2 Temporal scales, baselines and dimensions of integration

ACCEPTED VERSION SUBJECT TO FINAL EDITING

The concept of a unified and seamless framework for weather and climate prediction (Brown et al., 2012a; Hoskins, 2013) provides the context for understanding and simulating regional climate across multiple spatial and temporal scales. This concept is embodied in the subseasonal-to-seasonal (Vitart et al., 2017) and the seasonal-to-multiannual (Smith et al., 2020) prediction activities that generate regional climate information across temporal scales. The seamless framework benefits from the convergence of methods traditionally used in weather forecasting and climate projections, in particular the role of the initialization in climate models and the strategies for the evaluation of physical processes relevant at different temporal scales.

The relatively short observational record (Section 10.2, Chapter 2) is a primary challenge to estimate the forced signal and to isolate low-frequency, multi-decadal and longer term internal variability (Frankcombe et al., 2015; Overland et al., 2016; Bathiany et al., 2018). Because only one realization of the actual climate exists, it is nontrivial to extract estimates of internal and forced variability from the available data (Frankcombe et al., 2015). As an alternative, approaches that use large observational ensembles can be applied (Section 10.4; McKinnon and Deser, 2018).

There is a close relationship between spatial and temporal scales (Figure 10.3). For example, an individual convective storm may exhibit scales of variability ranging from metres and seconds to kilometres and hours, while for El Niño-Southern Oscillation (ENSO) the scales of variability are regional to hemispheric in extent and multi-year in length. These scales interact and the interactions are represented in climate models, although the ability of current models to simulate regional phenomena and even large-scale climate drivers still leaves room for improvement (Section 10.3) and limits their capability to represent the interactions across spatial and temporal scales.

It is important to note that in this chapter and subsequent regional chapters, including the Interactive Atlas, the baselines and reference periods used for climate change estimates from regional models may vary from those used in Chapters 1–9. In these chapters three main time baselines are defined for the past, i.e., pre-industrial (1750), early-industrial (1850–1900) and recent (1995–2014), while the future reference periods are 2021–2040 (near term), 2041–2060 (mid-century) and 2081–2100 (long term) (Section 1.4.1, Cross-Chapter Box 1.2). Regional climate simulations used in the recent literature have been performed with different baselines. The differences are often due to the availability of the boundary conditions from global simulations, leading to periods chosen for those simulations like 1950–2005, in line with the CMIP5 historical simulations followed by projections from 2005 onwards (Vaittinada Ayar et al., 2016; Dong-feng et al., 2017; Cai et al., 2018a). For simulations that use CMIP3 boundary conditions other periods have been used. As a consequence, these regional simulations mix for the recent period historical simulations with projections. The mismatch needs to be considered when assessing results obtained from both global and regional models in the context of the climate information distillation process, or when linking the regional chapters to the assessments performed in previous chapters. The choice of baseline provides a source of uncertainty for the assessment of climate impacts (e.g., for the response of bird species in Africa; Baker et al., 2016). Besides, a range of different baselines may need to be considered to satisfy a variety of users, since this choice affects the perceived result (Dobor and Hlásny, 2018). The influence of the different baseline periods can be explored using the Interactive Atlas where different baselines are available, for example, 1986-2005 (according to AR5), 1995-2014 (AR6), and both 1961-1990 and 1981-2010 (WMO).

One way of overcoming the baseline uncertainty is to define the results for a given model based on specific global-mean temperature changes from the pre-industrial period (e.g., Sylla et al., 2018a for West Africa; Kjellström et al., 2018 for Europe; Taylor et al., 2018 for the Caribbean; Montroull et al., 2018 for South America). The specific global-mean temperature is known as global warming level (GWL; Sections 1.6.2 and 10.6.4, Cross-Chapter Box 11.1). The GWL is a useful dimension of integration because important changes in regional climate, including many types of extremes, scale quasi-linearly with the GWLs, often independently of the underlying emissions scenarios (e.g., Hoegh-Guldberg et al., 2018; Beusch et al., 2020; Seneviratne and Hauser, 2020), taking always into account caveats described in Cross-Chapter Box 11.1. In addition, GWLs allow a separated analysis of the global and regional climate responses associated with a warming level (Seneviratne and Hauser, 2020; Section 10.6.4). The choice of global temperature goal in the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

context of the 2015 Paris Agreement means that there is an increasing desire for the regional climate information to be expressed as a function of GWLs.

10.1.3 Sources of Regional Climate Variability and Change

Variability in regional climate arises from natural and anthropogenic forcings, internal variability including the local expression of large-scale remote drivers (also known as teleconnections), and the feedbacks between them. Due to the many possible drivers of variability and change (Figure 10.3), quantifying the interplay between internal modes of decadal variability and any externally forced component is crucial in attempts to attribute causes of regional climate changes (e.g., Hoell et al., 2017; Nath et al., 2018). A regional climate signal could arise purely due to some anthropogenic influence or conversely, entirely due to internal variability, but it is most likely the result of a combination of both (Section 10.4). This section briefly introduces these sources of regional variability and should be read along with corresponding sections in Chapters 3, 6 and 7. Section 10.3 assesses their representation in climate models, Section 10.4 discusses their relevance for the attribution of multi-decadal trends and Section 10.6 refers to them as sources in specific examples where regional climate information is built. Section 8.2 offers a companion discussion focussing on changes in the water cycle. An example of how changes in one region could act as a source for changes in a neighbouring one is assessed in the Cross-Chapter Box 10.1 for the linkages between polar and mid-latitude regions, an interaction that has led to substantial recent research. This section also introduces the sources of uncertainty in model-derived regional climate information and how the quantification of the uncertainties influences the confidence of the regional climate information.

10.1.3.1 Forcings controlling regional climate

There are important differences in the processes affected by greenhouse gases (GHGs) over land and ocean. Over the ocean, the increased radiative forcing leads to an increase in latent heat flux and a decrease in sensible heat flux, while over land, water availability is limited and increased radiative energy is therefore converted mostly into sensible heat (Sutton et al., 2007). Notably, this leads to preferential warming of the land regions, which are themselves skewed towards the Northern Hemisphere.

Variations in solar forcing (Section 2.2.1) could influence regional climate through its modulation of circulation patterns, although this research field is still hampered by large observational and modelling uncertainties. The 11-year solar cycle has been suggested to affect the leading atmospheric circulation modes of the North Atlantic region in model based studies (Gray et al., 2013; Thiéblemont et al., 2015; Sjolte et al., 2018). In particular the solar cycle has been suggested as an important source of near-term predictability of the North Atlantic Oscillation (NAO; Kushnir et al., 2019), while other studies have not found evidence for links between the solar cycle and NAO in observational records (Ortega et al., 2015; Sjolte et al., 2018; Chiodo et al., 2019). On centennial time scales, solar fluctuations were found to be correlated with the Eastern Atlantic Pattern (Sjolte et al., 2018). Possible influences on winter circulation and temperature over Eurasia (Chen et al., 2015) and North America (Liu et al., 2014; Li and Xiao, 2018) have also been identified.

An updated assessment of past changes in stratospheric ozone can be found in Section 2.2.5.2. AR6 assesses that both GHG and stratospheric ozone depletion have contributed to the expansion of the zonal mean Hadley cell in the Southern Hemisphere for the period 1981–2000 with *medium confidence* (Section 3.3.3) (Garfinkel et al., 2015; Waugh et al., 2015; Grise et al., 2019). There is *medium confidence* that stratospheric ozone depletion contributed to the strengthening trend of the summer SAM for the period 1970-1990, but this influence has been weaker since 2000 (Section 3.7.2). The poleward shift of the Southern Hemisphere westerlies has also been explained by stratospheric ozone depletion (Solman and Orlanski, 2016). Section 10.4 assesses its role in the multi decadal increase of rainfall in Southeastern South America and Section 10.6.2 does so for the occurrence of the Cape Town drought.

Both natural and anthropogenic aerosols are often emitted at a regional scale, have a short atmospheric

ACCEPTED VERSION SUBJECT TO FINAL EDITING

lifetime (from a few hours to several days; Section 6.1), are dispersed regionally and affect climate at a regional scale through radiative cooling/heating and cloud microphysical effects (Rotstayn et al., 2015; Sherwood et al., 2015; Chapter 8). The majority of aerosols scatter solar radiation, but with strong regional variations (Shindell and Faluvegi, 2009) that lead to regional radiative effects of up to two orders of magnitude larger than the global average (Li et al., 2016c, 2016a; Mallet et al., 2016). Black carbon, instead, is known to absorb solar radiation, leading to regional atmospheric warming patterns due to its inhomogeneous spatial distribution (Gustafsson and Ramanathan, 2016). Patterns of forcing generally follow those of aerosol burden. However, temperature and precipitation responses are both local and remote (Li et al., 2016d; Kasoar et al., 2018; Liu et al., 2018c; Samset et al., 2018; Thornhill et al., 2018; Westervelt et al., 2018). For instance, changes in aerosol concentrations in the Northern Hemisphere have been reported to modulate monsoon precipitation in West Africa and the Sahel (Undorf et al., 2018; Section 10.4.2.1) and in Asia (Zhang et al., 2018; Section 10.6.3).

Natural aerosols include mineral dust, volcanic aerosol and sea salt. The feedback processes between climate and mineral dust as well as sea salt are assessed in Section 6.4, while the volcanic aerosol is dealt with in Cross-Chapter Box 4.1. Mineral dust created by wind erosion of arid and semi-arid surfaces dominates the aerosol load over some areas. The major sources of contemporary dust are located in the arid topographic basins of Northern Africa, Middle East, Central and Southwest Asia, the Indian subcontinent, and East Asia (Prospero et al., 2002; Ginoux et al., 2012) and emissions are controlled by changes in surface winds, precipitation, and vegetation (Ridley et al., 2014; Wang et al., 2015a; DeFlorio et al., 2016; Evan et al., 2016; Pu and Ginoux, 2018). Dust both scatters and absorbs radiation and serves as nuclei of warm and cold clouds (Chapter 6). The surface direct radiative effect is likely negative over land and ocean, especially when the assumed solar absorption by dust is large (Miller et al., 2014; Strong et al., 2015). Surface temperature and precipitation adjust to the direct radiative effect with both sign and magnitude depending on the dust absorptive properties. Dust often cools the surface, but in regions such as the Sahara surface air temperature increases as the shortwave absorption by dust is increased, leading to increases of surface temperature over the major reflective dust sources (Miller et al., 2014; Solmon et al., 2015; Strong et al., 2015; Jin et al., 2016; Sharma and Miller, 2017).

Volcanic eruptions load the atmosphere with large amounts of sulphur, which is transformed through chemical reactions and micro-physics processes into sulphate aerosols (Cross-Chapter Box 4.1; Stoffel et al., 2015; LeGrande et al., 2016). If the plume reaches the stratosphere, sulphate aerosols can remain there for months or years (about two to three for large eruptions) and can then be transported to other areas by the Brewer-Dobson circulation. If the eruption occurs in the tropics, its plume is dispersed across the Earth in a few years, while if the eruption occurs in the high latitudes, aerosols mainly remain in the same hemisphere (Pausata et al., 2015). The global temperature response observed after the last five major eruptions of the last two centuries is estimated to be around -0.2°C (Swingedouw et al., 2017), in association with a general decrease of precipitation (Iles and Hegerl, 2017). Nevertheless, the statistical significance of the regional response remains difficult to evaluate over the historical era (Bittner et al., 2016; Swingedouw et al., 2017) due to the small sampling of large volcanic eruptions over this period and the fact that the signal is superimposed upon relatively large internal variability (Gao and Gao, 2018; Dogar and Sato, 2019). Evidence from paleoclimate observations is therefore crucial to obtain a sufficient signal-to-noise ratio (Sigl et al., 2015). Reconstructed modes of climate variability based on proxy records allow evaluation of the influence on those modes (Zanchettin et al., 2013; Ortega et al., 2015; Michel et al., 2018; Sjolte et al., 2018).

Anthropogenic aerosols play a key role in climate change (Chapter 6). Although the global mean optical depth caused by anthropogenic aerosols did not change from 1975 to 2005 (Chapter 6), the regional pattern changed dramatically between Europe and eastern Asia (Fiedler et al., 2017, 2019; Stevens et al., 2017). Large regional differences in present-day aerosol forcing exist with consequences for regional temperature, hydrological cycle and modes of variability (Chapter 8, Section 10.6). Examples of regions with a notable role for anthropogenic aerosol forcing are the Indian monsoon region (Section 10.6.3) and the Mediterranean basin (Section 10.6.4). Anthropogenic aerosols are also very relevant in many urban areas (Box 10.3; Gao et al., 2016; Kajino et al., 2017).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

SRCCL assessed that nearly three-quarters of the land surface is under some form of land use, particularly in agriculture and forest management (Jia et al., 2019). The effects of land management on climate are much less studied than land cover effects although net cropland has changed little over the past 50 years, while land management has continuously changed (Jia et al., 2019). Section 7.3.4.1 assesses the global influence of both land use and irrigation on the effective radiative forcings. Land cover changes and land management can influence climate locally, such as the urban heat island and non-locally as in the case of increased rainfall downwind of a city (Jia et al., 2019, Box 10.3) or the monsoon circulation affected by irrigation (Section 10.6.3). The influence of land cover changes and land management on regional climate extremes is assessed in Section 11.1.6.

It is *very likely* that the global land surface air temperature response to urbanization is negligible (Chapter 2, Section 2.3.1.1.3). However, there is evidence that urbanization may regionally amplify the air temperature response to climate change in different climatic zones (Mahmood et al., 2014), either under present (Doan et al., 2016; Kaplan et al., 2017; Li et al., 2018c) or future climate conditions (Argüeso et al., 2014; Kim et al., 2016; Kusaka et al., 2016; Grossman-Clarke et al., 2017; Krayenhoff et al., 2018). For instance, in northern Belgium, (Berckmans et al., 2019) found that including urbanization scenarios for the near future (up to 2035) have a comparable influence on minimum temperature (increasing it by 0.6ºC) to that of the GHG-induced warming under RCP8.5.

10.1.3.2 Internal drivers of regional climate variability

Internal climate variability on seasonal to multi-decadal temporal scales is substantial at regional scales. This variability arises from internal modes of atmospheric and oceanic variability, intrinsically coupled climate modes, and may additionally be driven by processes other than those originating the modes. It also interacts with the response of the climate system to external forcing. The teleconnections associated with the modes are useful to understand the relationship between large and regional scales (Annex IV). A description of various large-scale modes of variability can be found in Chapters 2, 3 and 8, and in Annex IV, while their future projections are assessed in Chapter 4. The specificities of their regional influence are briefly discussed here. More details of their typical temporal scales and regional influences can be found in Annex IV.

Atmospheric modes of variability may have seasonally-dependent regional effects like the North Atlantic Oscillation (NAO) in European winter (Tsanis and Tapoglou, 2019) and summer (Bladé et al., 2012; Dong et al., 2013). Even though these modes are internal to the climate system, their variability can be affected by anthropogenic forcings. For instance, the Southern Annular Mode (SAM; Hendon et al., 2014) is both internally driven (Smith and Polvani, 2017), but also affected by recent stratospheric ozone changes (Bandoro et al., 2014). The teleconnections between these modes of variability and surface weather often exhibit considerable non-stationarity (Hertig et al., 2015).

Due to the large ocean heat capacity and their long temporal scales, multiannual to multi-decadal modes of ocean variability such as the Pacific Decadal Variability (PDV; Newman et al., 2016) and the Atlantic Multidecadal Variability (AMV; Buckley and Marshall, 2016) are key drivers of regional climate change. In the case of the AMV both natural (volcanic) and anthropogenic (aerosol) external forcings are thought to be involved in its timing and intensity (Section 3.7.7). These modes not only affect nearby regions but also remote parts of the globe through atmospheric teleconnections (Meehl et al., 2013; Dong and Dai, 2015) and can act to modulate the influence of natural and anthropogenic forcings (Davini et al., 2015; Ghosh et al., 2017; Ménégoz et al., 2018b). The dynamics of the ocean modes is simultaneously affected by other modes of variability spanning the full range of spatial and temporal scales due to non-linear interactions (Kucharski et al., 2010; Dong et al., 2018) (Figure 10.3). This mutual interdependence can result in changing characteristics of the connection over time (Gallant et al., 2013; Brands, 2017; Dong and McPhaden, 2017), and of their regional climate impact (Martín-Gómez and Barreiro, 2016, 2017). As with atmospheric modes of variability, the regional influence of ocean modes of variability on regional climates can be seasonally dependent (Haarsma et al., 2015).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.1.3.3 Uncertainty and confidence

Uncertainty and confidence are treated in the same way in regional climate change information as in larger-scale (continental and global) climate problems (Chapter 1, Section 10.3.4). The degree of confidence in climate simulations and in the resulting climate information typically depends on the identification of the role of the uncertainties (Section 10.3.4). Since the direct verification of simulations of future climate changes is not possible, model performance and reliable (i.e., trustworthy) uncertainty estimates need to be assessed indirectly through process understanding and a systematic comparison with observations of past and current climate (Section 10.3.3; Eyring et al., 2019; Knutti et al., 2010). The observational uncertainty, which is particularly large at regional scales, also has to be taken into account (Section 10.2). These uncertainty estimates are then propagated in the distillation process to generate climate information (Smith and Matthews, 2015).

Uncertainties in model-based future regional climate information arise from different sources and are introduced at various stages in the process (Lehner et al., 2020): 1) forcing uncertainties associated with the future scenario or pathway that is assumed, 2) internal variability, and 3) uncertainties related to imperfections in climate models, also referred to as structural or model uncertainty. However, the relative role of each of these sources of uncertainty differs between the global and the regional scales as well as between variables and also between different regions (Lehner et al., 2020). One way to address the internal variability and model uncertainties is to consider results from both multiple models and multiple realizations of the same model (Eyring et al., 2016a; Díaz et al., 2020; Lehner et al., 2020). These models are at times also combined with different weights that are a function of their performance and independence to increase the confidence of the multi-model ensemble (Abramowitz et al., 2019; Brunner et al., 2019).

Other elements that play a role are the inconsistency between the global and regional models in dynamical downscaling or the observational and methodological uncertainty in bias-adjustment methods (Sørland et al., 2018). These elements, in addition to those typical of the uncertainty in global and large-scale phenomena (Chapters 1–9), affect the overall confidence of regional climate information. This complex scene with different sources of uncertainty makes the collection of results available from multi-model, multi-member simulations most useful when synthesized through a distillation process (Section 10.5.3).

10.1.4 Distillation of Regional Climate Information

Regional climate information is synthesized from different lines of evidence from a number of sources (Sections 10.2–10.4) taking into account the context of a user vulnerable to climate variability and change at regional scales (Baztan et al., 2017) and the values of all relevant actors (Corner et al., 2014; Bessette et al., 2017) in a process called distillation (Section 10.5). Distillation, understood as the process of synthesizing information about climate change from different lines of evidence obtained from a variety of sources and taking into account the user context and the values of all relevant actors, allows the connection of global climate change to the local and regional scales, where adaptation responses and policy decisions take place. Climate information is translated into the user context in a co-production process that introduces further user-relevant elements leading to user-relevant climate information (Figure 10.1; Pettenger, 2016; Verrax, 2017) for a specific demand like, for instance, guiding climate-resilient development (Kruk et al., 2017; Parker and Lusk, 2019).

The approaches adopted in the distillation of regional climate information are diverse and range from the simple delivery of data as information to co-production with the user using as many lines of evidence as possible (Lourenço et al., 2016). The availability and selection of the sources and the approach followed has implications for the usefulness of the information. For instance, it is well established that it is invalid to take a time series from a grid cell of a model simulation as equivalent to an observational estimate of a point within the cell, due to the lack of representativeness (Section 10.3), and consequently the information building solely on this type of data source is of limited use. Relevant decisions are made during the distillation process such as what method is most suitable to a specific user context and the question being addressed. The information may be provided in the form of summarised raw data, a set of user-oriented

ACCEPTED VERSION SUBJECT TO FINAL EDITING

indicators, a set of figures and maps with either a brief description, in the form of a storyline, or formulated as rich and complex climate adaptation plans. The information typically includes a description of the sources and assumptions, estimates of the associated uncertainty and its sources, and guidance to prevent possible misunderstandings in its communication.

The choices made for the distillation have typically been part of a linear supply chain, starting from the access to climate data that are transformed into maps or derived climate data products, and finally formulating statements that are communicated and delivered to a broad range of users (Hewitt et al., 2012; Hewitson et al., 2017). This methodology has proven to be valuable in many cases, but it is equally fraught with dangers of not communicating important assumptions, not estimating the impact of relevant uncertainties, and possibly causing misunderstandings in the hand-over to the user community. This has led to the emergence of new pathways to generate user-oriented climate information, many in the context of emerging climate services (Buontempo et al., 2018; Hewitt et al., 2020), which are assessed in Section 10.5 and in Chapter 12.

10.1.5 Regional Climate Information in the WGI AR6

This chapter is part of a cluster devoted to regional climate (10, 11, 12 and Atlas). It introduces many of the aspects relevant to the generation of regional climate information that are dealt with in detail elsewhere. Figure 10.4 summarizes how these chapters relate to one another and to the rest of the report.

Chapter 11 assesses observed, attributed and projected changes in weather and climate extremes, provides a mechanistic understanding on how changes in extremes are related to human-induced climate change and provides regional, continental and global-scale assessments on changes in extremes, including compound events. Chapter 12 identifies elements of the climate system relevant for sectoral impacts referred to as climatic impact-drivers (CIDs), assesses past and future evolutions of sector-relevant CIDs for each AR6 region, synthesizes such evolutions for different time periods and by GWL, and assesses how CIDs are used in climate services. The Atlas assesses observed, attributed and projected changes in mean climate, performs a comparison of CMIP5, CMIP6 and CORDEX simulations, evaluates downscaling performance and assesses approaches to communicate climate information. The Interactive Atlas facilitates the exploration of datasets assessed in all chapters through a wide range of maps, graphs and tables generated in an interactive manner. This allows for the comparison of changes at warming levels and scenario/time-period combinations, display of indices for extremes and CIDs, and serves all chapters in the report to facilitate synthesis information and support the Technical Summary and the Summary for Policymakers.

Other chapters also include a strong regional component and provide context for the assessment of regional climate. Chapter 1 introduces the different types of climatic regions used in WGI AR6 and the main types of climatic models. Chapter 2 describes the recent and current state of the climate from observations, most of which are key for the production of regional information. Chapter 3 assesses human influences on the climate system and Chapter 4 assesses climate-change projections, with a global focus. These three chapters include phenomena that are important for shaping regional climate such as general circulation, jets, storm tracks, blocking and modes of variability. At the same time, the visualization of information in global maps in these chapters provides valuable information for the sub-continental scale. Chapter 5 assesses the knowledge about the carbon and biogoechemical cycles, whose fluxes and responses show variability that is strongly regional in nature. Chapter 6 assesses the regional evolution of short-lived climate forcers as well as their influence on regional climate and air quality. Chapter 8 assesses observed and projected changes in the variability of the regional water cycle, including monsoons, while changes of the regional oceans, changes in cryosphere and regional sea level change are assessed in Chapter 9.

[START BOX 10.1 HERE]

BOX 10.1: Regional climate in AR5 and the Special Reports SRCCL, SROCC and SR1.5

This box summarizes the information on linking global and regional climate change information in the Fifth Assessment Report (AR5) and the three Special Reports of the Sixth Assessment Cycle. This information frames the treatment of the production of regional climate information in previous reports and identifies some of the gaps that AR6 needs to address.

AR5

In the WGI Chapter 9 (Flato et al., 2014), regional downscaling methods were addressed as tools to provide climate information at the scales needed for many climate impact studies. The assessment found *high confidence* that downscaling adds value both in regions with highly variable topography and for various small-scale phenomena. Regional models necessarily inherit biases from the global models used to provide boundary conditions. Furthermore, the ability of AR5 to systematically evaluate RCMs, and statistical downscaling schemes, were hampered because coordinated inter-comparison studies were still emerging. However, several studies demonstrated that added value arises from higher resolution in regions where stationary small-scale features like topography and complex coastlines are present, and from improved representation of small-scale processes like convective precipitation.

WGI Chapter 14 (Christensen et al., 2013) stressed that credibility in regional climate change projections increases when key drivers of the change are known to be well-simulated and well-projected by climate models.

The Working Group II (WGII) Chapter 21 (Hewitson et al., 2014b) addressed the regional climate change context from the perspective of impacts, vulnerability and adaptation. This chapter emphasized that a good understanding of decision-making contexts is essential to define the type and scale of information required from physical climate. Further, the chapter identified that the regional climate information was limited by the paucity of comprehensive observations and their analysis along with the different levels of confidence in projections (*high confidence*). Notably, at the time of the AR5, many studies still relied on global datasets, models, and assessment methods to inform regional decisions, which were not considered as effective as tailored regional approaches. The regional scale was not defined but instead it was emphasised that climate change responses play out on a range of scales, and the relevance and limitations of information differ strongly from global to local scales, and from one region to another.

Chapter 21 noted that the production of downscaled datasets (by both dynamical and statistical methods) remains weakly coordinated, and that results indicate that high-resolution downscaled reconstructions of the current climate can have significant errors. Key in this was that the increase in downscaled data sets has not narrowed the uncertainty range, and that integrating these data with historical change and process-based understanding remains an important challenge.

The chapter identified the common perception that higher resolution (i.e., more spatial detail) equates to more usable and robust information, which is not necessarily true. Instead, it is through the integration of multiple sources of information that robust understanding of change is developed.

WGII Chapter 21 highlighted that the different contexts of an impact study are defining features for how climate risk is perceived. Perspectives were characterized as top-down (physical vulnerability) and bottom-up perspectives (social vulnerability). The top-down perspective uses climate change impacts as the starting point of how people and/or ecosystems are vulnerable to climate change, and commonly applies global-scale scenario information or refine this to the region of interest through downscaling procedures. Conversely, in the “bottom-up” approach the development context is the starting point, focusing on local scales, and layers

ACCEPTED VERSION SUBJECT TO FINAL EDITING

climate change on top of this. An impact focus tends to look to the future to see how to adjust to expected changes, whereas a vulnerability-focused approach is centred on addressing the drivers of current vulnerability.

Special Report on Climate Change and Land (SRCCL; IPCC, 2019a)

The SRCCL (Jia et al., 2019) assessed that there is *robust evidence and high agreement* that land cover and land use or management exert significant influence on atmospheric states (e.g., temperature, rainfall, wind intensity) and phenomena (e.g., monsoons), at various spatial and temporal scales, through their biophysical influences on climate. There is *robust evidence* that dry soil moisture anomalies favour summer heat waves. Part of the projected increase in heat waves and droughts can be attributed to soil moisture feedbacks in regions where evapotranspiration is limited by moisture availability (*medium confidence*). Vegetation changes can also amplify or dampen extreme events through changes in albedo and evapotranspiration, which will influence future trends in extreme events (*medium confidence*).

The influence of different changes in land use (e.g., afforestation, urbanization), on the local climate depends on the background climate (*robust evidence, high agreement*). There is *high confidence* that regional climate change can be dampened or enhanced by changes in local land cover and land use, with sign and magnitude depending on region and season.

Water management and irrigation were generally not accounted for by CMIP5 global models available at the time of the SRCCL. Additional water can modify regional energy and moisture balance particularly in areas with highly productive agricultural crops with high rate of evapotranspiration. Urbanization increases the risks associated with extreme events (*high confidence*). Urbanization suppresses evaporative cooling and amplifies heatwave intensity (*high confidence*) with a strong influence on minimum temperatures (*very likely*, *high confidence*). Urban areas enhance storm occurrence and heavy precipitation in part due to the presence of aerosols. Urbanization also increases the risk of flooding during heavy rain events.

Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC; IPCC, 2019b)

The SROCC (IPCC, 2019b) stated that observations and models for assessing changes in the ocean and the cryosphere have been developed considerably during the past century but observations in some key regions remain under-sampled and were very short relative to the time scales of natural variability and anthropogenic changes. Retreat of mountain glaciers and thawing of mountain permafrost continues and will continue due to significant warming in those regions, where it is *likely* to exceed global temperature increase.

SROCC assessed that it is *virtually certain* that Antarctica and Greenland have lost mass over the past decade and observed glacier mass loss over the last decades is attributable to anthropogenic climate change (*high confidence*). It is *virtually certain* that projected warming will result in continued loss in Arctic sea ice in summer, but there is *low confidence* in climate model projections of Antarctic sea ice change because of model biases and disagreement with observed trends. Knowledge and observations of the polar regions were sparse compared to many other regions, due to remoteness and challenges of operating in them.

The sensitivity of small islands and coastal areas to increased sea level differs between emission scenarios and regionally and a consideration of local processes is critical for projections of sea level influences at local scales.

Special Report on Global Warming of 1.5°C (SR1.5; IPCC, 2018b)

The SR1.5 (Hoegh-Guldberg et al., 2018) assessed that most land regions were experiencing greater warming than the global average, with annual average warming already exceeding 1.5°C in many regions. Over one quarter of the global population live in regions that have already experienced more than 1.5°C of warming in at least one season. Land regions will warm more than ocean regions over the coming decades (transient climate conditions).

Transient climate projections reveal observable differences between 1.5°C and 2°C global warming in terms of mean temperature and extremes, both at a global scale and for most land regions. Such studies also reveal detectable differences between 1.5°C and 2°C precipitation extremes in many land regions. For mean

ACCEPTED VERSION SUBJECT TO FINAL EDITING

precipitation and various drought measures there is substantially lower risk for human systems and ecosystems in the Mediterranean region at 1.5°C compared to 2°C.

The different pathways to a 1.5ºC warmer world may involve a transition through 1.5°C, with both short and long-term stabilization (without overshoot), or a temporary rise and fall over decades and centuries (overshoot). The influence of these pathways is small for some climate variables at the regional scale (e.g., regional temperature and precipitation extremes) but can be very large for others (e.g., sea level).

[END BOX 10.1 HERE]

[START CROSS-CHAPTER BOX 10.1 HERE]

Cross-Chapter Box 10.1: Influence of the Arctic on mid-latitude climate

Coordinator: Rein Haarsma (Netherlands)
Contributors: Francisco Doblas-Reyes (Spain), Hervé Douville (France), Nathan Gillett (Canada), Gerhard Krinner (France), Dirk Notz (Germany), Krishnan Raghavan (India), Alexander C. Ruane (USA), Sonia I. Seneviratne (Switzerland), Laurent Terray (France), Cunde Xiao (China)

The Arctic has *very likely* warmed more than twice the global rate over the past 50 years with the greatest increase during the cold season (Atlas 11.2). Several mechanisms are responsible for the enhanced lower troposphere warming of the Arctic, including ice-albedo, lapse rate, Planck and cloud feedbacks (Section 7.4.4.1). The rapid Arctic warming strongly affects the ocean, atmosphere, and cryosphere in that region (Atlas 11.2, Section 2.3.2.1). Averaged over the decade 2010-2019, monthly-average sea ice area in August, September and October has been about 25% smaller than that during 1979-1988 (*high confidence*, Section 9.3.1.1). It is *very likely* that anthropogenic forcings mainly due to greenhouse gas increases have contributed substantially to Arctic sea ice loss since 1979, explaining at least half of the observed long-term decrease in summer sea-ice extent (Section 3.4.1.1).

In this box, the possible influences of the Arctic warming on the lower latitudes is assesed. This linkage was also the topic of the Box 3.2 of the Special Report on the Ocean and Cryosphere in a Changing Climate (SROCC; IPCC, 2019b). It is a topic that has been strongly debated (Ogawa et al., 2018; Wang et al., 2018a). Separate hypotheses have emerged for winter and summer that describe possible mechanisms of how the Arctic can influence the weather and climate at lower latitudes. They involve changes in the polar vortex, storm tracks, jet stream, planetary waves, stratosphere-troposphere coupling, and eddy-mean flow interactions, thereby affecting the mid-latitude atmospheric circulation, and the frequency, intensity, duration, seasonality and spatial extent of extremes and climatic impact-drivers like cold spells, heat waves, and floods (Cross-Chapter Box 10.1, Figure 1). However, we note that a decrease in the intensity of cold extremes has been observed in the Northern Hemisphere mid-latitudes in winter since 1950 (van Oldenborgh et al., 2019; Section 11.3.2). Since SROCC new literature has appeared, and the mechanisms and their criticisms are assessed here as an update and extension to the SROCC box.

[START CROSS-CHAPTER BOX 10.1, FIGURE 1 HERE]

Cross-Chapter Box 10.1, Figure 1: Mechanisms of potential influences of recent and future Arctic warming on mid-latitude climate and variability. Mechanisms are different for winter and summer with different associated influences on mid-latitudes. The mechanisms involve changes in the polar vortex, storm tracks, planetary waves and jet stream.

[END CROSS-CHAPTER BOX 10.1, FIGURE 1 HERE]

Mechanisms for a potential influence in winter

ACCEPTED VERSION SUBJECT TO FINAL EDITING

It has been proposed that Arctic amplification, by reducing the equator-pole temperature contrast, could result in a weaker and more meandering jet with Rossby waves of larger amplitude (Francis et al., 2017). This may cause weather systems to travel eastward more slowly and thus, all other things being equal, Arctic amplification could lead to more persistent weather patterns over the mid-latitudes (Francis and Vavrus, 2012). The persistent large meandering flow may increase the likelihood of connected patterns of temperature and precipitation climatic impact-drivers because they frequently occur when atmospheric circulation patterns are persistent, which tends to occur with a strong meridional wind component. Another possible consequence of Arctic warming is on the NAO/AO that shows a negative trend over the past two decades (Robson et al., 2016; Iles and Hegerl, 2017), and has been linked to the reduction of sea ice in the Barents and Kara seas, and the increase in Eurasian snow cover (Cohen et al., 2012; Nakamura et al., 2015; Yang et al., 2016). During negative NAO/AO the storm tracks shift equatorward and winters are predominantly more severe across northern Eurasia and the eastern United States, but relatively mild in the Arctic. This temperature pattern is sometimes referred to as the "warm Arctic–cold continents (WACC)" pattern (Chen et al., 2018). However, Sun et al. (2016a) noticed that the WACC is a manifestation of natural variability. Enhanced sea-ice loss in the Barents-Kara Sea has also been related to a weakening of the stratospheric polar vortex (Kretschmer et al., 2020) and its increased variability (Kretschmer et al., 2016) that would induce a negative NAO/AO (Kim et al., 2014), the WACC pattern (Kim et al., 2014), and an increase in cold-air outbreaks in mid-latitudes (Kretschmer et al., 2018). Arctic warming might also increase Eurasian snow cover in autumn caused by the moister air that is advected into Eurasia from the Arctic with reduced sea-ice cover (Cohen et al., 2014; Jaiser et al., 2016), although Peings (2019) suggests a possible influence of Ural blockings on both the autumn snow cover and the early winter polar stratosphere. The circulation changes over the Ural-Siberian region are also suggested to provide a link between Barents-Kara sea ice and the NAO (Santolaria-Otín et al., 2021).

Mechanisms for a potential influence in summer

As in winter, Arctic summer warming may result in a weakening of the westerly jet and mid-latitude storm tracks, as suggested for the recent period of Arctic warming (Coumou et al., 2015; Petrie et al., 2015; Chang et al., 2016). Additional proposed consequences are a southward shift of the jet (Butler et al., 2010) and a double jet structure associated with an increase of the land-ocean thermal gradient at the coastal boundary (Coumou et al., 2018). It is hypothesized that weaker jets, diminished meridional temperature contrast, and reduced baroclinicity might induce a larger amplitude in stationary wave response to stationary forcings (Zappa et al., 2011; Petoukhov et al., 2013; Hoskins and Woollings, 2015; Coumou et al., 2018; Mann et al., 2018; Zhang et al., 2020b), and also that a double jet structure would favour wave resonance (Kornhuber et al., 2017; Mann et al., 2017). Some studies suggest that this is corroborated by an observed increase of quasi-stationary waves (Di Capua and Coumou, 2016; Vavrus et al., 2017; Coumou et al., 2018).

Assessment

The above proposed hypotheses are based on concepts of geophysical fluid dynamics and surface coupling and can, in principle, help explain the existence of a link between the Arctic changes and the mid-latitudes with the potential to affect many impact sectors (Barnes and Screen, 2015). However, the validity of some dynamical underlying mechanisms, such as a reduced meridional temperature contrast inducing enhanced wave amplitude, has been questioned (Hassanzadeh et al., 2014; Hoskins and Woollings, 2015). On the contrary, the reduced meridional temperature contrast has been related to reduced meridional temperature advection and thereby reduced winter temperature variability (Collow et al., 2019).

Studies that support the Arctic influence are mostly based on observational relationships between the Arctic temperature or sea-ice extent and mid-latitude anomalies or extremes (Cohen et al., 2012; Francis and Vavrus, 2012, 2015; Budikova et al., 2017). They are often criticised for the lack of statistical significance and the inability to disentangle cause and effect (Barnes, 2013; Barnes and Polvani, 2013; Screen and Simmonds, 2013; Barnes et al., 2014; Hassanzadeh et al., 2014; Barnes and Screen, 2015; Sorokina et al., 2016; Douville et al., 2017; Gastineau et al., 2017; Blackport and Screen, 2020a; Oudar et al., 2020; Riboldi et al., 2020). The role of the Barents-Kara Sea ice loss is challenged by Blackport et al. (2019) who find a minimal influence of reduced sea ice on severe mid-latitude winters, and by Warner et al. (2019) who suggest that the apparent winter NAO response to the Barents-Kara sea-ice variability is mainly an artefact of the Aleutian Low internal variability and of the co-variability between sea ice and the Aleutian Low

ACCEPTED VERSION SUBJECT TO FINAL EDITING

originating from tropical-extratropical teleconnections. Also Gong et al. (2020) do not find a link between Rossby wave propagation into the midlatitudes and Arctic sea ice loss. Mori et al. (2019a) argue that models underestimate the influence of the Barents-Kara Sea ice loss on the atmosphere, which is disputed by Screen and Blackport (2019). Other studies have stressed the importance of atmospheric variability as a driver of Arctic variability (Lee, 2014; Woods and Caballero, 2016; Praetorius et al., 2018; Olonscheck et al., 2019). Analysing observed key variables of mid-latitude climate for 1980-2020, Blackport and Screen (2020b) and Riboldi et al. (2020) argue that the Arctic influence on mid-latitudes is small compared to other aspects of climate variability, and that observed periods of strong correlation are an artefact of internal variability or intermittency (Kolstad and Screen, 2019; Siew et al., 2020; Warner et al., 2020).

An additional argument in the criticism is the inability of climate models to simulate a significant response to Arctic sea-ice loss, larger than the natural variability (Screen et al., 2014; Walsh, 2014; Chen et al., 2016a; Peings et al., 2017; Dai and Song, 2020), although some studies find a significant response in summer, because then the internal variability is weaker (Petrie et al., 2015).

Finally, a warmer Arctic climate can, without any additional changes in atmospheric dynamics, reduce cold extremes in winter due to advection of increasingly warmer air from the Arctic into the mid-latitudes (Screen, 2014; Ayarzagüena and Screen, 2016; Ayarzagüena et al., 2018).

Summarizing, different hypotheses have been developed about the influence of recent Arctic warming on the mid-latitudes in both winter and summer. Although some of the proposed mechanisms seem to be supported by various studies, such as the link with Barents-Kara Sea ice loss in winter and weakened storm tracks in summer, the underlying mechanisms and relative strength compared to internal climate variability have been questioned. A recent review (Cohen et al., 2020) states that divergent conclusions between model and observational studies, and also between different model studies, continue to obfuscate a clear understanding of how Arctic warming is influencing mid-latitude weather. In this context, Shepherd (2016) stresses the need for collaboration between scientists with different viewpoints for further understanding that could be achived by carefully designed, multi-investigator, coordinated, multi-model simulations, data analyses and diagnostics (Overland et al., 2016). In agreement with Box 3.2 of SROCC, there is hence *low to medium confidence* in the exact role and quantitative effect of historical Arctic warming and sea-ice loss on mid-latitude atmospheric variability.

Regarding future climate, it is important to note that mid-latitude variability is also affected by many drivers other than the Arctic changes and that those drivers as well as the linkages to mid-latitude variability might change in a warmer world. The AMV, PDV, ENSO (see Annex IV), upper tropospheric tropical heating, polar stratospheric vortex, and land-surface processes associated with soil moisture (Miralles et al., 2014; Hauser et al., 2016) are a few examples. A considerable body of literature has shown that changes to the NAO/AO on seasonal and climate change time scales can be driven by variations in the wavelength and amplitude of Rossby waves, mainly of tropical origin (Fletcher and Kushner, 2011; Cattiaux and Cassou, 2013; Ding et al., 2014; Goss et al., 2016). The influence of future Arctic warming on mid-latitude circulation is difficult to disentangle from the effect of such a plethora of drivers (Blackport and Kushner, 2017; Li et al., 2018a). One of the consequences of climate change is a poleward shift of the jet induced by the tropical warming (Barnes and Polvani, 2013), which is less obvious in winter especially over the North Atlantic (Peings et al., 2018; Oudar et al., 2020), and the increase of the meridional temperature gradient in the upper troposphere, which increases storm track activity (Barnes and Screen, 2015). Although climate models indicate that future Arctic warming and the associated equator-pole temperature gradient could affect mid-latitude climate and variability (Haarsma et al., 2013b; McCusker et al., 2017; Zappa et al., 2018), and even the tropics and sub-tropics (Deser et al., 2015; Cvijanovic et al., 2017; Wang et al., 2018; England et al., 2020; Kennel and Yulaeva, 2020), they do not reveal a strong influence on extreme weather (Woollings et al., 2014).

In conclusion, there is *low confidence* in the relative contribution of Arctic warming to mid-latitude atmospheric changes compared to other drivers. Future climate change could affect mid-latitude variability in a number of ways that are still to be clarified, and which may also include the influence of Arctic warming. The linkages between the Arctic warming and the mid-latitude circulation is an example of

ACCEPTED VERSION SUBJECT TO FINAL EDITING

contrasting lines of evidence that cannot yet be reconciled (Section 10.5).

[END CROSS-CHAPTER BOX 10.1 HERE]

10.2 Using Observations for Constructing Regional Climate Information

Considerable challenges (and opportunities) remain in using observations for climate monitoring, for evaluating and improving climate models (Section 10.3.1), for constructing reanalyses and post-processing model outputs, and therefore, ultimately, for increasing our confidence in the attribution of past climate changes and in future climate projections at the regional scale. While an assessment of large-scale observations can be found in Chapter 2 (Cross-Chapter-Box 2.2, Section 2.3), this section discusses the specific aspects of the observations at regional scale and over the typological regions considered in the regional chapters (Section 10.1.5). This section focuses on land regions and does not consider the specific requirements of ocean observations (see Chapter 9 and the SROCC for more information on this aspect).

10.2.1 Observation Types and Their Use at Regional Scale

10.2.1.1 In situ and remote-sensing data

Surface or in situ observations can come from a variety of networks: climate reference networks, mesoscale weather and supersite observation networks, citizen science networks, among others, all with their strengths and weaknesses (McPherson, 2013; Thorne et al., 2018). Supersite observatories are surface and atmospheric boundary layer observing networks that measure a large number of atmospheric and soil variables at least hourly over a decade or more, ideally located in rural areas (Ackerman and Stokes, 2003; Haeffelin et al., 2005; Xie et al., 2010; Chiriaco et al., 2018). Adequate calibration of instruments, quality control and homogenization are essential in these sites. They produce valuable data needed to diagnose processes and changes in regional and local climate. Several climate datasets have been developed from in situ station observations, at different spatial scales and temporal frequencies (Annex I). These include sub-daily (Dumitrescu et al., 2016; Blenkinsop et al., 2017), daily (Aalto et al., 2016; Funk et al., 2015; Beck et al., 2017a, 2017b; Camera et al., 2014; Chen et al., 2008; Journée et al., 2015; Schneider et al., 2017), or monthly time scales (Aryee et al., 2018; Cuervo-Robayo et al., 2014). Sub-daily data is useful for estimating storm surge (Mori et al., 2014) or river discharge (Shrestha et al., 2015), daily data for carbon-stock dynamics (Haga et al., 2020) or tourism (Watanabe et al., 2018), and monthly data for beach morphology (Bennett et al., 2019).

Satellite products provide a valuable complement to in situ measurements, particularly over regions where in situ measurements are unavailable. They have been discussed in earlier chapters (e.g., Chapters 2 and 8) for large-scale assessment. Currently 54 essential climate variables (ECVs; Bojinski et al., 2014) are defined by the Global Climate Observing System (GCOS) program, and passed on, for example, to NASA programmes through the Decadal Survey, to the Copernicus Climate Change Service of the European Union, to the ESA Climate Change Initiative ESA-CCI, as well as to the international collaborations with geostationary Earth-orbit (GEO) satellites. Their observations are valuable (*high confidence*) for regional applications since they provide multi-channel images at very high spatiotemporal resolutions, typically 16 channels, 1–2 km, every 10 to 15 minutes. The advanced geostationary satellites are: Himawari-8 and 9 (Kurihara et al., 2016), GOES-East and GOES-17 (Goodman et al., 2018), Meteosat-10 and 11 (Schmetz et al., 2002) and FY-4 (Cao et al., 2014). Geostationary satellite networks or constellations form an essential component of the Global Observation System (https://www.wmo.int/pages/prog/www/OSY/GOS.html), providing measurements not only for various cloud properties and moisture but also for air quality, land and ocean surface conditions, and lightning.

Low Earth-orbit (LEO) satellites, with orbits typically at 400-700 km, provide advanced measurements of the Earth's surface. Sun-synchronous polar orbiters can also cover the polar regions, which cannot be observed with GEO satellites. Examples of LEO observations for land-surface monitoring are NASA's

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Landsat (Wulder et al., 2016), ESA's Soil Moisture Ocean Salinity Earth Explorer (SMOS) mission (Kerr et al., 2012), the Sentinel missions of the Copernicus programme, and JAXA's ALOS-2 (Ohki et al., 2019), providing high spatial resolution land-surface images. Many kinds of data are accumulated for land use and land cover studies, targeting aspects like urban footprint (Florczyk et al., 2019), land-cover data (Global Land 30; CCI-LC: https://www.esa-landcover-cci.org; Chen and Chen,2018), land-surface temperature data (LANDSAT, Parastatidis et al., 2017), and surface albedo (Chrysoulakis et al., 2019).

Availability of active sensors on LEO satellites enables measurement of microphysical properties of aerosol, cloud and precipitation, which can advance regional climate studies and process evaluation studies to improve regional climate models (*high confidence*). An example is the polar-orbiting "afternoon-train" satellite constellation (known as the A-train), incorporating Aqua, CALIPSO, Cloudsat, PARASOL, Glory and Aura satellites. Vertical profiling observations from Cloudsat (with a W-band cloud radar) and CALIPSO (with a cloud lidar) led to considerable advances in measurements of cloud microphysics (Stephens et al., 2018). Precipitation and its extremes are essential concerns of regional climate studies. The GPM (65°N–65°S, 2014–present) and the preceding TRMM (36.5°N–36.5°S, 1997–2015) with Ku-/Ka-band precipitation radars have provided three-dimensional measurements of precipitation with ~5 km resolution and sub-daily sampling (Skofronick-Jackson et al., 2017). Their non-sun synchronous observation works to cross-calibrate the constellation satellites to produce global high-resolution mapped products of precipitation, such as Integrated Multi-satellitE Retrievals for GPM (IMERG; Huffman et al., 2007) and the Global Satellite Mapping of Precipitation (GSMaP; Kubota et al., 2007), with hourly sampling at ~11 km resolution. The CPC MORPHing technique (CMORPH) has provided 30 min interval global precipitation with ~8 km coverage since 2002 (Joyce et al., 2004). Precipitation estimations from Remotely Sensed Information using Artificial Neural Networks (PERSIANN) is a sub-daily to daily rainfall product that covers 50°S to 50°N globally with 25 km resolution from 2000 to the present (Nguyen et al., 2019), and is used for semi-global scale precipitation coverage (Benestad, 2018). TRMM/GPM observations have enabled estimates to be obtained for global four-dimensional convective heating (Shige et al., 2009; Tao et al., 2016; Takayabu and Tao, 2020).

The use of these data has enhanced our understanding of precipitation processes at regional scale (*high confidence*), such as diurnal cycles in a large river valley (Chen et al., 2012b), and in coastal (Hassim et al., 2016; Yokoi et al., 2017) and mountainous regions (Hirose et al., 2017). Three-dimensional observations revealed the contrasts in regional characteristics of rainfall extremes in monsoon regions and continental dry regions (Sohn et al., 2013; Hamada and Takayabu, 2018). Satellite measurements are also used to evaluate climate model performance, as well as to develop new parameterizations. As a demonstration of the utility of these products in studying model bias, a subtropical cumulus congestus regime has been identified that may be implicated in the unrealistic double ITCZ found in some climate models (Takayabu et al., 2010; Hirota et al., 2011, 2014). Another example is a parameterization of a land-surface model that was developed specifically for a certain soil type. By assimilating satellite brightness temperature observations with their LDAS-UT scheme, Yang et al., (2007) successfully optimized a land-surface model for the Tibetan Plateau.

For application at a regional scale, it is important to consider variations in the spatiotemporal resolution of the satellite products. A simple concatenation of data in time can show artificial jumps that are artefacts of changes in calibration and processing algorithms, or related to satellite orbital stability or changing performance of the instruments (Wielicki et al., 2013; Barrett et al., 2014). Recalibration and cross-calibration are then prerequisites for obtaining homogeneous time series of measurements across different or successive satellites that can then be used to produce long series that are valid as climate data records (Kanemaru et al., 2017; Merchant et al., 2017). Scale representativeness is also an issue in utilizing soil observations (Taylor et al., 2012, 2013). Although a variety of technologies to measure soil moisture at the point scale exist (Dobriyal et al., 2012), its spatial representativeness is less than 1 m^2 (Ochsner et al., 2013; Liu et al., 2016b). Therefore, to be able to use in situ soil moisture for validating coarser-scale data from satellites or models, networks of point-scale measurements are used (Crow et al., 2015; Polcher et al., 2016). Smaller networks are typically of the size of a single climate model grid cell or a satellite pixel and are suitable for monitoring watersheds, while small numbers of those representing larger areas (>100 km^2) are emerging (Ochsner et al., 2013).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.2.1.2 Derived products

Derived observational products are created from raw datasets collected from surface stations, remote-sensing instruments, or research vessels, which are converted into meaningful physical quantities by applying a suitable measurement theory, using either statistical interpolation techniques (Section 10.2.2.4) or numerical atmospheric and land-surface models (Bosilovich et al., 2015).

Most global observational datasets are available at coarse temporal and spatial resolution, and do not include all available station data from a particular region, due to data availability problems. Therefore, efforts have been made to develop regional or country-scale datasets (Annex I). Radar and satellite remote sensing are resources that can provide a valuable complement to direct measurements at regional scale. Examples for precipitation have been described already, some of which have been released to the community (Bližňák et al., 2018; Dietzsch et al., 2017; Dinku et al., 2014; Krähenmann et al., 2018; Manz et al., 2016; Oyler et al., 2015; Panziera et al., 2018; Shen et al., 2018; Yang et al., 2017). However, some of these datasets are limited by their short record, varying between one (Shen et al., 2018) and 64 years (Oyler et al., 2015).

Reanalysis products are numerical climate simulations that use data assimilation to incorporate as many irregular observations as possible. These products encompass many physical and dynamical processes. They generate a coherent estimate of the state of the climate system on uniform grids either at global (Balsamo et al., 2015; Chaudhuri et al., 2013), regional (Chaney et al., 2014; Dahlgren et al., 2016; Maidment et al., 2014; Mahmood et al., 2018; Attada et al., 2018; Langodan et al., 2017) or country scales (Krähenmann et al., 2018; Mahmood et al., 2018; Rostkier-Edelstein et al., 2014).

Reanalyses incorporate an increasing volume of observations from a growing number of sources over time, which sometimes presents a difficulty for trend analysis. However, regional reanalyses are valuable for regional climate assessments, since they can employ high-resolution model simulations due to their limited spatial domain. Their accuracy is also better than global reanalyses since they are often developed over regions with a high density of observational data (sometimes not freely available for all regions) to be assimilated into the model (e.g., Yamada et al., 2012). Regional reanalyses can assimilate locally dense and high-frequency observations, such as from local observation networks (Mahmood et al., 2018; Su et al., 2019) and radar precipitation (Wahl et al., 2017) in addition to the observations assimilated by global reanalyses. In some regional reanalyses, satellite-derived high-resolution sea ice (Bromwich et al., 2016, 2018) and sea surface temperature (Su et al., 2019) are also applied as lower boundary conditions. The periods of regional reanalyses are limited by the availability of the observations for assimilation and by the global reanalyses needed as lateral boundary conditions. Most regional reanalyses cover the past 10 to 30 years. There are also regional reanalysis activities that use conventional observations only, which produce consistent datasets over 60 years to capture precipitation trends, extremes and changes (Fukui et al., 2018). Existing regional reanalyses cover North America (Mesinger et al., 2006), Europe (Dahlgren et al., 2016; Jermey and Renshaw, 2016; Kaspar et al., 2020), the Arctic (Bromwich et al., 2016, 2018), South Asia (Mahmood et al., 2018), and Australia (Su et al., 2019). A project for regional reanalysis covering Japan has also started (Fukui et al., 2018), where grid spacing is between 5 and 32 km, although cumulus parameterizations are still needed to compute sub-grid scale cumulus convection. Recently, reanalyses using convection-permitting regional models have been published (e.g., Wahl et al., 2017, for central Europe).

The data assimilation schemes used in regional reanalyses are often relatively simple methods, specifically nudging (Kaspar et al., 2020) and 3DVAR (Mesinger et al., 2006; Bromwich et al., 2016; Dahlgren et al., 2016), rather than the more complex schemes implemented in state-of-the-art global reanalysis systems. This is partly due to limitations of computational resources. Recently, a number of regional reanalyses using more sophisticated methods, such as 4DVAR and Ensemble Kalman filter, have been published (Jermey and Renshaw, 2016; Fukui et al., 2018; Mahmood et al., 2018; Su et al., 2019). The regional reanalyses also incorporate uncertainties due to deficiencies of the models, data assimilation schemes and observations. To estimate uncertainties, some regional reanalyses apply data assimilation using ensemble forecasts (Bach et al., 2016). Another approach compares multiple regional reanalyses produced with different systems covering the same domain, which represents the uncertainties better than single reanalysis systems with

ACCEPTED VERSION SUBJECT TO FINAL EDITING

ensemble data assimilation schemes (Kaiser-Weiss et al., 2019).

The regional reanalyses represent the frequencies of extremes and the distributions of precipitation, surface air temperature, and surface wind better than global reanalyses (*high confidence*). This is due to the use of high-resolution regional climate models (RCMs), as indicated by different regional climate modelling studies (Mesinger et al., 2006; Bollmeyer et al., 2015; Bromwich et al., 2016, 2018; Dahlgren et al., 2016; Jermey and Renshaw, 2016; Fukui et al., 2018; Su et al., 2019). Regional reanalyses, however, retain uncertainties due to deficiencies in the physical parametrization used in RCMs and by the use of relatively simple data assimilation algorithms (Bromwich et al., 2016; Jermey and Renshaw, 2016; Su et al., 2019). Regional reanalyses can provide estimates that are more consistent with observations than dynamical downscaling approaches, due to the assimilation of additional local observations (*high confidence*) (Bollmeyer et al., 2015; Fukui et al., 2018).

10.2.2 Challenges for Regional Climate Change Assessment

10.2.2.1 Quality control

The usefulness of any observational dataset is conditioned by the availability and outcome of a quality control (QC) process. The objective of the QC is to verify that data are representative of the measured variable and to what degree the value could be contaminated by unrelated or conflicting factors (WMO, 2017a). Data quality assessment is key for ensuring that the data are credible and to establish trusted relationships between the data provider and the users (Nightingale et al., 2019). QC is performed for all relevant global climate datasets (e.g., Menne et al., 2018). For instance, QC informs users that old reanalysis datasets can be inconsistent in the long term because they assimilated inhomogeneous observations over the reanalyses period (Kobayashi et al., 2015). As a consequence, the evaluation against independent observations suggests that reanalyses should not be automatically regarded as climate-quality products for monitoring long-term trends at the regional level (Manzanas et al., 2014; Torralba et al., 2017). QC needs to be systematically carried out by the institutions responsible for handling the data (e.g. Cao et al., 2016).

The QC procedure depends strongly on the specific nature of the dataset. It focuses on aspects such as the correct identification of sensor, time and location, detection of unfeasible or inconsistent data, error estimation, assessment of the adequacy of the uncertainty information and the adequacy of the documentation (e.g., Heaney et al., 2016). QC principles also apply to model data (Tapiador et al., 2017). An important piece of information provided is the representativeness error (Section 10.2.1.1; Gervais et al., 2014). When problems in the data representativeness are identified, observational datasets are provided with a quality mask (Contractor et al., 2020), or the problematic data are either removed or corrected (Ashcroft et al., 2018). These are factors often taken into account in constructing regional climate information (Kotlarski et al., 2019).

Quality-controlled data are now produced widely at the regional level, as in the case of sub-daily precipitation records in the United Kingdom (Blenkinsop et al., 2017) and the USA (Nelson et al., 2016). However, many more datasets and variables lack the same level of scrutiny (Alexander, 2016). Quality-controlled, high-resolution observational datasets are especially needed at regional and local scales to assess models as their resolution increases (Di Luca et al., 2016; Zittis and Hadjinicolaou, 2017), although the awareness and appropriate use of the QC information is challenging (Tapiador et al., 2017) when generating regional climate information (*high confidence*).

10.2.2.2 Homogenization

Homogenization aims to make data spatially and temporally “homogeneous”. Changes in a homogeneous time series are solely due to large-scale climatic changes (whether forced or due to internal variability). Station data are influenced by factors that act at regional scales, from the mesoscale and local scale down to the microscale (WMO, 2019). Station time series contain inhomogeneities such as artificial jumps or trends,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

which hamper assessments of regional long-term trends. Typical reasons for this are the urbanization of a station's surroundings, which can lead to warming (Hamdi, 2010; Hansen et al., 2010; Adachi et al., 2012; Jones, 2016; Sun et al., 2016b), or relocations outside of the urban area, which could lead to cooling (Tuomenvirta, 2001; Yan et al., 2010; Xu et al., 2013; Dienst et al., 2017, 2019). Another potential source of inhomogeneity is a change in measurement methods that affect most instruments of an observational network over a limited time span, such as the transition to Stevenson screens (Parker, 1994; Böhm et al., 2010; Brunet et al., 2011; Auchmann and Brönnimann, 2012) or to automatic weather stations (WMO, 2017b).

The above examples have been selected as they are present in many stations and without going through homogenization they could potentially have influenced global land warming estimates (Section 1.5.1). Single-break inhomogeneities tend to have a magnitude comparable to global climate change (Tuomenvirta, 2001; Venema et al., 2012) and are thus important for analyses of small regions. Also station records in national networks often have similar changes, making them important for national climate change estimates, but many of these influences are averaged out at the global scale (Jones, 2016).

The main approach to reduce the influence of inhomogeneities in station observations is statistical homogenization by comparing the data from a candidate station with those of neighbouring reference stations in conjunction with the use of metadata (Trewin, 2010). This is a challenging task because both reference and candidate records normally have multiple inhomogeneities. Three challenges should be considered. First, most of our understanding of statistical homogenization stems from the homogenization of temperature observations from dense networks. Recent studies suggest that our ability to remove biases quickly diminishes for sparse networks (Gubler et al., 2017; Lindau and Venema, 2018a). This affects early instrumental data and observations that are not strongly correlated between stations, such as wind and humidity (Chimani et al., 2018).

Second, in addition to systematic errors, homogenized data also suffer from random errors, introduced by the homogenization process. These errors are largest at the station level but are also present in network-averaged signals (Lindau and Venema, 2018b). These errors are determined by the break time series, as well as the noise series and the performance of the homogenization method, are spatially correlated, and have an impact on activities such as interpolation and statistical post-processing of climate simulations (Section 10.2.3.1). Third, the above discussion pertains to the homogenization of monthly and annual means. Homogenization of daily variability around the mean is more difficult. For daily data, specific correction methods are used (Della-Marta and Wanner, 2006; Mestre et al., 2011; Trewin, 2013) that are able to improve the homogeneity of test cases, although recent independent validation efforts were not able to show much improvement (Chimani et al., 2018). The difference with homogenization methods of monthly and annual means may stem from assumptions on the nature of inhomogeneities for daily data, which are not yet well understood (Chimani et al., 2018).

It is *virtually certain* that statistical homogenization methods reduce the uncertainties of long-term estimates. Considering a decomposition of the long-term warming error into a bias and a noise uncertainty around the bias, the (trend) bias especially will be reduced, but also most of the noise uncertainty. This conclusion is based on our understanding of the causes of inhomogeneities and their statistical nature combined with the design principles of statistical homogenization methods, as well as on analytical (Lindau and Venema, 2018b), numerical (Venema et al., 2012; Williams et al., 2012) and empirical validation studies (Hausfather et al., 2016; Gubler et al., 2017; Killick et al., 2020).

The above section is about the homogenization of land stations. Satellite data has its own issues and methods for homogenization (Brinckmann et al., 2013; Huang et al., 2015; Brogniez et al., 2016). The homogenization of radiosonde data and land station data use similar methods (Haimberger et al., 2012; Jovanovic et al., 2017).

10.2.2.3 Data scarcity

Data scarcity arises largely due to the lack of maintenance of observing stations, inaccessibility of the data

ACCEPTED VERSION SUBJECT TO FINAL EDITING

held in national networks, and uneven spatial distribution of stations that lead to a low density in many regions. This is particularly problematic when trying to assess regional climate change, for which a high density of observational data is desirable. Although in several regions numerous stations provide (monthly) data covering more than 100 years for both temperature and precipitation (GCOS, 2015), large areas of the world remain sparsely covered. The post-1990 decline in the total number of stations contributing to the Global Precipitation Climatology Centre (GPCC) monthly product may be related to delays in data acquisition and not paucity of data (GCOS, 2015). This is because GPCC is the result of a single time scale, single Essential Climate Variable and single data collection centre. There is no similar drop-off of the rainfall reports in the Global Historical Climatology Network - Daily database (GHCND, Menne et al., 2012) or the Integrated Surface Database at the sub-daily time scale.

Kidd et al. (2017) made some assumptions about GPCC-available gauges and indicated that only 1.6% of Earth's surface lies within 10 km of a rain gauge, and many areas of the world are beyond 100 km from the nearest rain gauge. Data scarcity is especially critical over Africa (Nikulin et al. 2012, Dike et al., 2018) but the apparent data scarcity could be due to reasons other than actual paucity of data, as stated earlier. For instance, over South Africa, the number of weather stations collecting daily temperature used in the fourth version of the Climatic Research Unit Temperature dataset (CRUTEM4, Osborn and Jones, 2014) has significantly declined since 1980 (Archer et al., 2018). Although CRUTEM4 has now been replaced by CRUTEM5 (Osborn et al., 2021) it has yet to take advantage of the significant international efforts to curate and make available improved global holdings (Rennie et al., 2014) which increased the global available station count for monthly mean temperatures. This includes additional stations from many African countries. The apparent decline in stations since the 1980s could also be due to countries not contributing their data to the SYNOP/CLIMAT networks for reasons other than having non-operational stations.

Even in Europe, precipitation station density in the widely used E-OBS gridded dataset varies largely in space and time across regions (Prein and Gobiet, 2017). This variability is partly due to the reluctance of some data owners to share their data with an international effort. Regardless of the reason, low station density is a major source of uncertainty (Isotta et al., 2015). Kirchengast et al. (2014) and O and Foelsche (2018) found that at least 2 to 5 (12) stations are required for capturing the area-averaged precipitation amount of heavy summertime precipitation events on a daily (hourly) basis with a normalised root-mean-square error of less than 20%. Similar to the E-OBS dataset, gridded daily temperature and precipitation datasets are being developed for other regions of the world. Examples include Southeast Asia (SA-OBS, Van den Besselaar et al., 2017), and West Africa (WACA&D, Van Den Besselaar et al., 2015). Despite the uneven distribution of stations in space and time, the value in these initiatives is illustrated by the large number of studies in which the data product is used. This is the case, for instance, the work of Condom et al., (2020) over the Andes, a region with prominent data scarcity, and the African Monsoon Multidisciplinary Analysis Project over West Africa (e.g., Lebel and Ali, 2009). There have been efforts to reduce data scarcity through initiatives such as the International Surface Temperature Initiative (ISTI, Thorne et al., 2011), GHCND, and the Expanding Met Office Hadley Centre ISD with quality-controlled, sub-daily station data from 1931 (HadISD, Dunn et al., 2016).

Data scarcity arising from changing coverage in observation station networks results in substantial problems for climate monitoring (e.g., trend analysis of extreme events requires high temporal and spatial resolutions) or model evaluation (Section 10.3.3.1). It is *virtually certain* that the scarcity and decline of observational availability in some regions (but not necessarily globally), increase the uncertainty of the long-term global temperature and precipitation estimates. As an example, Lin and Huybers (2019) found that changes in the number of rain gauges after 1975 resulted in spurious trends in extremes of Indian rainfall in a 0.25°-gridded dataset spanning the 20th century. In fact, the number of stations used to construct the gridded dataset dropped by half after 1990, leading to inhomogeneity and spurious trends (Section 10.6.3). Over the southern part of the Mediterranean, which is an area sparsely covered by meteorological stations, data scarcity can lead to large uncertainties in the different gridded datasets and strongly affect model evaluation (Section 10.6.4). Perpetual data sparsity results in some climate characteristics not being observed (Yokoyama et al., 2019).

There are techniques for estimating and reconstructing missing data. The methods depend on the variable of

ACCEPTED VERSION
SUBJECT TO FINAL EDITING

interest, the temporal resolution (e.g., daily or monthly), and the type of climate (wet or dry), among others. There has been very little evaluation of the performance of classical and data mining methods (e.g., Sattari et al., 2017). The classical methods include the arithmetic mean, inverse-distance weighting method, multiple-regression analysis, multiple imputation, and single-best estimator, while the data-mining methods include multiple-perceptron artificial neural network, support-vector machine, adaptive neuro-fuzzy inference system, gene-expression programming method, and K-nearest neighbour. Crowd-sourced data (individuals contribute their own data points to create a dataset for others to use) could play a role in minimizing data scarcity (Section 10.2.4).

10.2.2.4 Gridding

Derived gridded datasets require merging data from different sources of observations and/or reanalysis data on a regular grid (e.g., Xie and Arkin, 1997; Section 10.2.1.2). However, in situ observations are distributed irregularly, especially over sparsely populated areas. This leads to an interpolation challenge. Gridded products of climate variables, including temperature and precipitation, are strongly affected (*high confidence*) by the interpolation method over complex orography and data scarce regions (Hofstra et al., 2008; Herrera et al., 2016).

There are two main approaches to produce gridded datasets: (1) based on in situ observations only, and (2) combining in situ observations with remote-sensing data and/or reanalysis data. The first approach has been widely employed in regions with high station density using interpolation techniques (such as inverse-distance weighting, optimal interpolation, and kriging) (Chen et al., 2008; Haylock et al., 2008; Frei, 2014; Isotta et al., 2014; Masson and Frei, 2014; Hiebl and Frei, 2016; Inoue et al., 2016). The second approach has been mainly applied in data-sparse regions with low station density, using simple bias adjustment, quantile mapping, and kriging techniques with in situ observations, remote-sensing and reanalysis data (Cheema and Bastiaanssen, 2012; Dinku et al., 2014; Abera et al., 2016; Erdin et al., 2012; Krähenmann et al., 2018).

Gridding of station data is affected by uncertainties stemming from measurement errors, inhomogeneities, the distribution of the underlying stations and the interpolation error, with station density being the dominant factor (Herrera et al., 2019). Uncertainty due to interpolation is typically small for temperature but substantial for precipitation and its derivatives, such as drought indices (Chubb et al., 2015; Hellwig et al., 2018). The largest uncertainties typically occur in sparsely sampled mountain areas (Section 10.2.2.5). Interpolation generally give rise to smoothing effects, such as low variability of the derived dataset with respect to the in situ observations (Chen et al., 2019). As a result, the effective resolution of gridded data is typically much lower than its nominal resolution. For instance, a 5 km gridded precipitation dataset for the European Alps has an effective resolution of about 10 to 25 km (Isotta et al., 2014). In an example for precipitation in Spain, the effective resolution converged to the nominal resolution only when at least 6 to 7 stations were inside the grid cell (Herrera et al., 2019). To account for the smoothing errors, new stochastic ensemble observation datasets have been introduced (Von Clarmann, 2014).

10.2.2.5 Observations in mountain areas

Spatiotemporal variability of meteorological parameters observed over mountainous areas is often large, indicating strong control exerted by local topography on meteorological parameters (Gultepe et al., 2014). Difficult access, harsh climatic conditions as well as instrumental issues make meteorological measurements extremely challenging at higher elevations (Azam et al., 2018; Beniston et al., 2018). Measurements of wind speed, temperature, relative humidity and radiative fluxes are critical for climate model evaluation, but difficult to handle due to their point-scale representativeness and small-scale spatiotemporal variability over mountainous terrain, and often need adjustment (Gultepe, 2015). High-altitude (>3000 metres) permanent meteorological stations are limited and current knowledge is mainly based on valley-bottom or low-elevation meteorological stations (Qin et al., 2009; Lawrimore et al., 2011; Gultepe, 2015; Condom et al., 2020), which, generally do not represent the higher elevation climate (Immerzeel et al., 2015; Shea et al., 2015).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Measuring precipitation amounts, especially of solid precipitation, in mountainous areas is particularly challenging due to the presence of orographic barriers, strong vertical and horizontal precipitation rate variability, and the difficulty in finding representative sites for precipitation measurements (Barry, 2012). However, the precipitation amounts can be indirectly estimated by the observed point mass balances at glacier accumulation areas representing net snow accumulation (Haimberger et al., 2012; Immerzeel et al., 2015; Sakai et al., 2015; Azam et al., 2018). There is *very high confidence* that precipitation measurements, especially solid precipitation, in mountainous areas are strongly affected by the gauge location and setup. Precipitation measurements are also affected by the type of measurement method, presence/absence of shielding, presence/absence of a heating system and operating meteorological conditions (Nitu et al., 2018). Solid precipitation measurements may have errors ranging from 20% to 50%, largely due to under-catch in windy, icing and riming conditions (Rasmussen et al., 2012), and therefore require corrections by applying transfer functions developed mainly from collected wind speed and temperature data (Kochendorfer et al., 2017). The latest Solid Precipitation Intercomparison Experiment report recommends measurements of wind speed, wind direction and temperature as the minimum standard ancillary data for solid precipitation monitoring (Nitu et al., 2018).

Recent advancements through remote-sensing methods provide an alternative, but they also have limitations over mountainous areas. Different versions of TRMM products were found to perform differently over mountainous areas (Zulkafli et al., 2014). Orographic heavy rainfall associated with Typhoon Morakot in 2009 was severely underestimated in all microwave products including TRMM 3B42 (Shige et al., 2013). The underestimation has been mitigated in the Global Satellite Mapping of Precipitation (GSMaP) product by considering the orographic effects (Shige et al., 2013). Studies have suggested a high accuracy of passive optical satellite (e.g., MODIS, Landsat) snow products under clear skies when compared with the field observations. However, cloud masking and sub-pixel cloud heterogeneity in these snow-cover products considerably restrict their applications (Kahn et al., 2011; Brun et al., 2015; Tang et al., 2017; Stillinger et al., 2019). Gridded datasets (e.g., CRU, GPCC Full Data Product, GPCC Monitoring Product, ERA-Interim, ERA5, ERA5-land, MERRA-2, MERRA-2 bias adjusted, PERSIANN-CDR) are of paramount importance, yet they often lack enough in situ observations to improve the temporal and spatial distribution of meteorological parameters over complex mountain terrain (Zandler et al., 2019).

10.2.2.6 Structural uncertainty

Beyond climate monitoring, the quality and availability of multiple observational reference datasets play a central role in model evaluation. In fact, when using observations for model evaluation, there are multiple examples where inter-observational uncertainty is as large as the inter-model variability. This has been shown for various aspects of the Indian monsoon (Section 10.6.3) (Collins et al., 2013a) and for precipitation uncertainties over Africa (Section 10.6.4) (Nikulin et al., 2012; Sylla et al., 2013; Dosio et al., 2015; Bador et al., 2020) and Europe (Prein and Gobiet, 2017). Kotlarski et al. (2019) compared three high-resolution observational temperature and precipitation datasets (E-OBS, a compilation of national/regional high-resolution gridded datasets, and the EURO4M-MESAN 0.22° reanalysis based on a high-resolution limited-area model) with five EURO-CORDEX RCMs driven by ERA-Interim. Generally, the differences between RCMs are larger than those between observation datasets, but for individual regions and performance metrics, observational uncertainty can dominate. They also showed that the choice of reference dataset can have an influence on the RCM performance score. Over the high mountain Asia region and East Asia, differences among gridded precipitation datasets can generate significant uncertainties in deriving precipitation characteristics (Kim et al., 2015b; Kim and Park, 2016; Guo et al., 2017). Over western North America, observational uncertainty induces differences in multi-decadal precipitation trends (Lehner et al., 2018). Taking a very different perspective, the agreement between model simulations may be used to estimate the uncertainty and quality of observations (Massonnet et al., 2016). There is *high confidence* that an ensemble of multiple observational references at a regional scale is fundamental for model performance assessment. The uncertainties vary according to region, season, and statistical properties (Cross-Chapter Box 10.2).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.2.3 Other Uses of Observations at Regional Scale

10.2.3.1 Observations for calibrating statistical methods

Statistical downscaling, bias adjustment and weather generators are post-processing methods used to derive climate information from climate simulations. They all require observational data for calibration as well as evaluation (Section 10.3.3.1). Typically, the so-called perfect prognosis methods use quasi-observations for the predictors (i.e., reanalyses) and actual observations for the predictands (the surface variables of interest). By contrast, bias adjustment methods use observations only for the predictands. Weather generators typically require only observed predictands, although some are conditioned on observed predictors as well. Very often these methods are based on daily data, because of user needs, but also because of the limited availability of sub-daily observations and the limited ability of climate models to realistically simulate sub-daily weather (Iizumi et al., 2012). Some methods are calibrated on the monthly scale, but some of the generated time series are then further disaggregated to the daily scale (e.g., Thober et al., 2014). A few methods, mainly weather generators, represent sub-daily weather (Mezghani and Hingray, 2009; Kaczmarska et al., 2014). Many methods simulate temperature and precipitation only, although some also represent wind, radiation and other variables. The limited availability of high quality and long observational records typically restricts these applications to a few cases (Verfaillie et al., 2017; Pryor and Hahmann, 2019). Overall, there is *high confidence* that limited availability of station observations, including variables beyond temperature and precipitation as well as sub-daily data, limit the use of statistical modelling of regional climate.

All the limitations and challenges of observational data discussed in Section 10.2.2 also apply to its use for post-processing of climate model data. High quality and long observational data series are particularly relevant to quantify uncertainties. Different reanalyses present significant discrepancies when used as key predictor variables at the daily scale and may even affect the downscaled climate change signal (Brands et al., 2012; Dayon et al., 2015; Manzanas et al., 2015; Horton and Brönnimann, 2019). There is *high confidence* that reanalysis uncertainties limit the quality of statistical downscaling in some regions, although no assessment has been made for the most recent reanalysis products.

An important issue for bias adjustment is the correct representation of the required spatial scale. Ideally, bias adjustment is calibrated against area-averaged data of the same spatial scale as the climate model output. Hence, high-quality observed gridded datasets with an effective resolution close to the nominal model resolution are required. Driven by the need to also generate regional-scale information in station-sparse regions, researchers have considered derived datasets that blend in situ and remote sensing data to produce high-resolution observations to be used as predictands (e.g., Haiden et al., 2011; Wilby and Yu, 2013) (Sections 10.2.1.2 and 10.2.2.4).

10.2.3.2 Observation for paleoclimate data assimilation

Following some early concept studies, the first practical applications of paleoclimate data assimilation over past centuries used only selected data to reconstruct past climate changes for analysis of a specific process or case (Widmann et al., 2010). Recently, assimilation of multiple series from various data sources, including tree rings, ice cores, lake cores, corals, and bivalves, has allowed production of reconstructions that can be widely shared and applied to multiple purposes, as with modern reanalyses (Franke et al., 2017; Hakim et al., 2016; Steiger et al., 2018, Tardif et al. 2019). Most of these paleo-reanalyses are global but there are products using regional models or targeted at specific regions such as Europe, East Africa and the Indian Ocean (Fallah et al., 2018; Klein and Goosse, 2018).

Paleo-reanalyses are enabling a new range of applications and have already provided useful information on seasonal-to-multidecadal climate variability over past millennia. They are useful tools to study the covariance between variables at interannual-to-centennial time scales and at regional to global spatial scales. In particular, they have highlighted the processes that can be responsible for changes in continental hydrology at multi-decadal time scales (Franke et al., 2017; Klein and Goosse, 2018; Steiger et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Paleo-reanalyses have confirmed a large contribution of internal variability in past changes at regional scale during the pre-industrial period, superimposed on a weak common signal due to forcing changes (Goosse et al., 2012) and the absence of a globally coherent warm period in the common era before the recent warming (Neukom et al., 2019). Reconstructions of the atmospheric state obtained in the reanalysis also provide robust evidence of a local enhancement of warming or cooling conditions due to changes in atmospheric circulation, such as for the warm conditions in some European regions around 950–1250 CE, the cooling observed in 1809/1810, or the cold and rainy 1816 summer in Europe (Cross-Chapter Box 4.1; Goosse et al., 2012; Hakim et al., 2016; Franke et al., 2017; Schurer et al., 2019).

10.2.4 Outlook for Improving Observational Data for Regional Climates

An encouraging development for understanding climate variations over the past 250 years or so at the global and regional scale lies in the field of data rescue, in which hitherto hidden archives of meteorological data are brought to the forefront (Sections 1.5.1.1 and 2.5). Surface observations from data rescue projects may then be assimilated to derive long-term high-resolution gridded surface regional reanalysis (Devers et al., 2020). Global extended reanalyses such as 20CR (Compo et al., 2011), ERA-20C (Poli et al., 2016b, 2016a) or CERA-20C (Laloyaux et al., 2018) may be further downscaled to quantify the variability of past climate at the regional scale (Caillouet et al., 2016, 2019).

One of the main scientific challenges related to high-resolution regional climate modelling is dealing with the representation of fine-scale processes (e.g., Yano et al., 2018) in observational data sets. Additionally, reliable observation networks following WMO standards have a very sparse geographical representation. Hence, regional climate models have started to use high-resolution data combined with crowdsourced observations (Zheng et al., 2018). Recent efforts have led to the production of homogeneously processed long-term datasets for regional climate model evaluation (Goudenhoofdt and Delobbe, 2016; Humphrey et al., 2017; Yang and Ng, 2019). While they are far less reliable and accurate than professional observations, crowdsourced data are abundantly available and can give spatial representations at very high resolution. This technological trend could prove very useful (*high confidence*), and the regional climate community is making efforts to understand the extent to which these data sources can be exploited, at least as a complement to traditional datasets (Overeem et al., 2013; Meier et al., 2017; Uijlenhoet et al., 2018; de Vos et al., 2019; Langendijk et al., 2019a).

10.3 Using Models for Constructing Regional Climate Information

Much of the information available on future regional climate arises from studies based on climate model simulations (Chapters 3, 4 and 8). In this section, different types of models (Section 10.3.1) and model experiments (Section 10.3.2) for generating regional climate information are discussed, followed by an assessment of the performance, added value, and fitness-for-purpose of different model types (Section 10.3.3). The focus is on the representation of large- to local-scale phenomena and processes relevant for regional climate. Finally, uncertainties of regional climate projections and methodologies to manage these are assessed (Section 10.3.4).

10.3.1 Model Types

Regional climate change information may be derived from a hierarchy of different model types covering a wide range of spatial scales and processes (Figure 10.5). The application of any model relies on assumptions, depending on the specific model as well as the application. Table 10.1 gives an overview of the generic assumptions of the different model types discussed here for generating regional climate information. The violation of these assumptions will affect the model performance, which is discussed in Section 10.3.3.

[START FIGURE 10.5 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 10.5: Typical model types and chains used in modelling regional climate. The dashed lines indicate model chains that might prove useful but have not or only rarely been used. Hybrid approaches combining the model types shown have been developed.

[END FIGURE 10.5 HERE]

[START TABLE 10.1 HERE]

Table 10.1: Assumptions underlying different model types in simulating regional climate and climate change. Violating these assumptions will affect model performance (see links to different subsections for details). All assumptions regarding future climate are in addition to those regarding present climate and predicated on the driving global model simulating a plausible global climate sensitivity (Section 1.3.5, Chapters 4 and 7). The assumptions listed for future climate applications of perfect prognosis statistical downscaling and bias adjustment are often called the "stationarity assumption". Numbers in curly brackets refer to chapters and sections assessing these assumptions.

Model type	Scale at which the assumption applies	Assumptions to realistically simulate present regional climate	Additional assumptions to be fit for simulating future regional climate
Global model (GCM or ESM; not bias adjusted) (Section 10.3.1.1)	Large (>1000km)	Global model includes all relevant large-scale forcings and realistically simulates relevant large-scale circulation {3.3.3, 8.5.1, 10.3.3.3}.	Global model realistically simulates processes controlling large-scale changes. Parameterisations are valid in future climate {Chapter 3, 4.2, 4.5, 8.5.1, 10.3.3.9}.
	Regional (<1000km)	Global model includes all relevant regional forcings and realistically simulates all relevant regional scale processes and feedbacks and their dependence on large-scale climate {8.5.1, 10.3.3.4-10.3.3.6, 10.3.3.8}.	Global model realistically simulates processes controlling regional changes. Parameterisations are valid in future climate {8.5.1, 10.3.3.9}.
Dynamical downscaling of global model with RCM (not bias adjusted) (Section 10.3.1.2)	Large	Driving global model includes all relevant large-scale forcings and realistically simulates relevant large-scale circulation, RCM does not deteriorate global simulations. Feedbacks from regional into large-scale processes are negligible {3.3.3, 8.5.1, 10.3.3.3}.	Driving global model realistically simulates processes controlling large-scale changes, RCM does not deteriorate global model changes. Parameterisations are valid in future climate {Chapter 3, 4.2, 4.5. 8.5.1, 10.3.3.9}.
	Regional	RCM includes all relevant regional forcings and realistically simulates all relevant regional scale processes and feedbacks and their dependence on large-scale climate {10.3.3.4–10.3.3.6, 10.3.3.8}.	RCM realistically simulates processes controlling regional changes. Parameterisations are valid in future climate {10.3.3.9}.
Perfect prognosis statistical	Large	Global model realistically simulates all relevant large-scale	Global model realistically simulates processes controlling

downscaling of GCM (Section 10.3.1.3)		predictors. The predictors are bias free and represent the regional variability at all desired time-scales {3.3.3, 8.5.1, 10.3.3.3}.	changes in the predictors. The predictors represent the response to external forcing {Chapter 3, 4.2, 4.5. 8.5.1, 10.3.3.9}.
	Regional	The statistical model structure is adequate to represent the predictor influence on regional-scale variability. There are no relevant feedbacks involving the predictands {10.3.3.7}.	The statistical model structure is adequate under the required extrapolation {10.3.3.9}.
Bias adjustment of dynamical model (GCM or RCM) (Section 10.3.1.3)	Large	As per driving model.	As per driving model.
	Regional	As per driving model, apart from adjustable biases. The gap between driving model resolution and target resolution is minor {10.3.3.4–10.3.3.6, 10.3.3.8, Cross-Chapter Box 10.2}.	As per driving model, apart from adjustable biases. The chosen bias adjustment is applicable in a future climate {10.3.3.9, Cross-Chapter Box 10.2}.
Delta change approach applied to dynamical model (Section 10.3.1.3)	Large	Not applicable	As per driving model. There are no changes altering the non-changed statistics (e.g., no circulation changes that alter temporal structure) {Chapter 3, 4.2, 4.5, 8.5.1, 10.3.3.9}.
	Regional	Not applicable	As per driving model. There are no changes altering the non-changed statistics. The gap between driving model resolution and target resolution is minor {10.3.3.9}.
Change factor weather generator applied to dynamical model (Section 10.3.1.3)	Large	Not applicable	As per driving model.
	Regional	The weather generator structure is adequate {10.3.3.7}.	As per driving model. The weather generator structure is adequate in a future climate. Change factors are adequately incorporated for all changing weather aspects. The gap between driving model resolution and target resolution is minor {10.3.3.9}.

[END TABLE 10.1 HERE]

10.3.1.1 Global models, including high-resolution and variable resolution models

Model-based regional climate projections are all based upon some type of global climate model, including state-of-the-art Earth system models (ESMs), coupled atmosphere-ocean general circulation models (GCMs) or atmosphere-only general circulation models (AGCMs) (see Section 1.5.3.1). They are collectively referred to as global models.

State-of-the-art global models are generally used to derive climate information at continental to global scales both for past and future climates (e.g., Chapters 3 and 4). The nominal horizontal resolution in CMIP5 global models is typically 100–200 km. The effective resolution, for which the shape of the kinetic energy spectrum is simulated correctly, is about 3 to 5 times larger (Klaver et al., 2020), and a similar relationship also applies to RCMs (Skamarock, 2004). This strongly limits their ability to resolve local details. Since AR5 the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

progress in reducing biases and providing more credible regional projections by global models has been moderate in spite of the more realistic representation of a number of processes and the increase in resolution of some models. For AR6, several of the new CMIP6 (Eyring et al., 2016a) model intercomparison projects (MIPs) address some of these limitations. The list of MIPs is provided in Chapter 1 (Table 1.3). HighResMIP (High-Resolution MIP; Haarsma et al., 2016) and GMMIP (Global Monsoons MIP; Zhou et al., 2016)) specifically address the regional climate challenge using global models. HighResMIP focuses on producing global climate projections at a horizontal resolution of around 50 km grid spacing or finer while GMMIP aims at better understanding and predicting the monsoons.

An alternative to increasing resolution everywhere is offered by variable resolution global models, that is, with regionally finer resolution. They have been developed since the 1970s (Li, 1999), resulting in a first coordinated effort (SGMIP) by Fox-Rabinovitz et al., (2006, 2008). They are expected to offer the finest resolution possible in the region of interest, while still resolving the climate processes at the global scale (although at lower resolution). An overview of recent developments is in McGregor (2015). This is a rapidly developing field (Krinner et al., 2014; Ferguson et al., 2016; Huang et al., 2016) that will possibly contribute to improved future regional projections.

10.3.1.2 RCMs

RCMs are dynamical models similar to GCMs that are applied over a limited area, but with a horizontal resolution higher than that of standard GCMs. They are the basis for dynamical downscaling to produce sub-continental climate information (e.g., Chapters 11, 12 and Atlas) but are also often used for process understanding. At lateral and, if applicable, lower boundaries, RCMs take their values from a driving data set, which could be a GCM or a reanalysis. RCMs are typically one-way nested: they do not feed back into the driving model, although two-way nested GCM-RCM simulations have been performed that examine regional influence on large-scale climate, potentially improving it (Lorenz and Jacob, 2005; Harris and Lin, 2013; Junquas et al., 2016). Spectral nudging (Kida et al., 1991; Waldron et al., 1996; von Storch et al., 2000; Kanamaru and Kanamitsu, 2007) can increase consistency with the driving model, whereby selected variables, such as the wind field, are forced to closely follow a prescribed large-scale field over a specified range of spatial scales. RCMs can inherit biases from the driving GCM in addition to producing biases themselves (Dosio et al., 2015; Hall, 2014; Hong and Kanamitsu, 2014; Takayabu et al., 2016). The consistency between the circulation features simulated by the RCM and those inherited through the boundary conditions depends on 1) the relative importance of the large-scale forcing compared to local-scale phenomena, and 2) the size of the RCM domain (e.g., Diaconescu and Laprise, 2013). Large domains also allow the RCM to generate much of its own internally generated unforced variability (Nikiema et al., 2017, and references therein; Sanchez-Gomez and Somot, 2018).

The CORDEX initiative (COordinated Regional climate Downscaling EXperiment; Giorgi et al., 2009; Giorgi and Gutowski, 2015; Gutowski Jr. et al., 2016) provides ensembles of high-resolution historical (starting as early as 1950) and future climate projections for various regions. RCMs in CORDEX typically have a horizontal resolution between 10 and 50 km. But much finer spatial resolution is required to fully resolve deep convection, an important cause of precipitation in much of the world. Therefore, an emerging strand in dynamical downscaling employs simulations at convection permitting scales, at horizontal resolutions of a few kilometres, where deep-convection parameterisations can be switched off, approximately simulating deep convection (Prein et al., 2015; Stratton et al., 2018; Coppola et al., 2020). A recent study indicates that switching off the deep-convection parameterization may be beneficial also in simulations performed at coarser resolutions (Vergara-Temprado et al., 2019). Alternatively, some RCMs make use of scale-aware parameterizations that are able to adapt to increasing resolution without switching off the convection scheme (Hamdi et al., 2012; De Troch et al., 2013; Plant and Yano, 2015; Giot et al., 2016; Termonia et al., 2018; Yano et al., 2018).

RCMs have often consisted of atmospheric and land components that do not include all possible Earth-system processes and therefore neglect important processes such as air-sea coupling (in standard RCMs sea surface temperatures, SSTs, are prescribed from GCM simulations or reanalyses) or the chemistry of cloud-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

aerosol interaction (aerosols prescribed with a climatology), which may influence regional climate projections. Therefore, some RCMs have been extended by coupling to additional components like interactive oceans, sometimes with sea ice (Kjellström et al., 2005; Somot et al., 2008; Van Pham et al., 2014; Sein et al., 2015; Ruti et al., 2016; Zou and Zhou, 2016a; Zou et al., 2017; Samanta et al., 2018), rivers (Sevault et al., 2014; Lee et al., 2015; Di Sante et al., 2019), glaciers (Kotlarski et al., 2010), and aerosols (Zakey et al., 2006; Zubler et al., 2011; Nabat et al., 2015). The coupling of these components allows for the investigation of additional climate processes such as regional sea-level change (Adloff et al., 2018), ocean-land interactions (Lima et al., 2019; Soares et al., 2019a), or the impact of high-frequency ocean-atmosphere coupling on the climatology of Mediterranean cyclones (Flaounas et al., 2018).

10.3.1.3 Statistical approaches to generate regional climate projections

An alternative or addition to dynamical downscaling is the use of statistical approaches to generate regional projections. In AR5 these methods were collectively referred to as statistical downscaling, but their performance assessment has received little attention. A major conclusion was that a wide range of different methods exist and a general assessment of their performance is difficult (Flato et al., 2014). Since AR5, several initiatives have been launched to improve the understanding of statistical approaches such as VALUE (now merged into EURO-CORDEX activities; Maraun et al., 2015), STARMIP (Vaittinada Ayar et al., 2016) and BADJAM (Galmarini et al., 2019). The performance of different implementations of these approaches will be assessed in Section 10.3.3.7.

10.3.1.3.1 Perfect prognosis

Perfect-prognosis models are statistical models calibrated between observation-based large-scale predictors (e.g., from reanalysis) and observed local-scale predictands (Maraun and Widmann, 2018b). Regional climate projections are then generated by replacing the quasi-observed predictors by those from climate model (typically global model) projections. Predictor patterns that are common to observations and climate model data can be defined by common empirical orthogonal functions (Benestad, 2011). The perfect prognosis approach can either be used to generate daily (or even sub-daily) time series, or local weather statistics (e.g., Benestad et al., 2018).

Regression-like models (Maraun and Widmann, 2018b) rely on a transfer function linking an observed local statistic (such as the temperature at a given day) to some set of large-scale predictors. Recent developments include stochastic regression models to explicitly simulate local variability (San-Martín et al., 2017; those explicitly modelling temporal dependence are assessed in Section 10.3.1.3.4). The use of machine learning techniques has been reinvigorated, including genetic programming to construct a data-driven model structure (Zerenner et al., 2016) and deep and convolutional neural networks (Reichstein et al., 2019; Baño-Medina et al., 2020).

Analogue methods (Martin et al., 1996; Maraun and Widmann, 2018b) compare a simulated large-scale atmospheric field with an archive of observations and select, using some distance metric, the closest observed field in the archive. The downscaled atmospheric field is then chosen as the local atmospheric field observed on the instant the analogue occurred. New analogue methods have been developed to simulate unobserved values including a rescaling of the analogue (Pierce et al., 2014) or by combining analogues and regression models (Chardon et al., 2018).

10.3.1.3.2 Bias adjustment

Bias adjustment is a statistical post-processing technique used to pragmatically reduce the mismatch between the statistics of climate model output and observations. The approach estimates the bias or relative error between a chosen simulated statistical property (such as the long-term mean or specific quantiles of the climatological distribution) and that observed over a calibration period; the simulated statistic is then adjusted taking into account the simulated deviation. Bias adjustment methods are regularly applied on a spatial scale similar to that of the simulation being adjusted, but they are often used as a simple statistical

ACCEPTED VERSION SUBJECT TO FINAL EDITING

downscaling method by calibrating them between coarse resolution (e.g., global) model output and finer observations (Maraun and Widmann, 2018b).

Typical implementations of bias adjustment are (1) additive adjustments, where the model data is adjusted by adding a constant, (2) rescaling, where the model data is adjusted by a factor, and (3) more flexible quantile mapping approaches that adjust different ranges of a distribution individually. Hempel et al. (2013), Pierce et al. (2015), Switanek et al. (2017), and (Lange, 2019) developed variants of quantile mapping that preserve trends in the mean or even further distributional statistics. Multivariate bias adjustment extends univariate methods, which adjust statistics of individual variables separately, to joint adjustment of multiple variables simultaneously. Implementations remove biases in (1) specific measures of multivariate dependence, like correlation structure, via linear transformations (Bárdossy and Pegram, 2012; Cannon, 2016), or, more flexibly, (2) the full multivariate distribution via nonlinear transformations (Vrac and Friederichs, 2015; Dekens et al., 2017; Cannon, 2018; Vrac, 2018; Robin et al., 2019). Other research strands focus on the explicit separation of bias adjustment and downscaling (Section 10.3.1.3.5), or the integration of process understanding (Maraun et al., 2017), such as by conditioning the adjustment on the occurrence of relevant phenomena (Addor et al., 2016; Verfaillie et al., 2017; Manzanas and Gutiérrez, 2019). Some authors suggest to mitigate the influence of large-scale temperature or circulation biases by performing a bias adjustment of the driving fields prior to dynamical downscaling (Colette et al., 2012; Hernández-Díaz et al., 2013, 2019). Issues that may arise when using bias adjustment are discussed in Cross-Chapter Box 10.2.

10.3.1.3.3 Delta-change approaches

In the delta change approach, selected observations are modified according to corresponding changes derived from dynamical model simulations. Traditionally, only long term means have been adjusted, but recently approaches to modify temporal dependence (Webber et al., 2018) have been developed, as well as quantile mapping approaches that individually adjust quantiles of the observed distribution (Willems and Vrac, 2011). By construction, the approach cannot modify the spatial and temporal dependence structure of the input observations (Maraun, 2016).

10.3.1.3.4 Weather generators

Weather generators are statistical models that simulate weather time series of arbitrary length. They are calibrated to represent observed weather statistics, in particular daily or even sub-daily variability. One variant of these models are advanced stochastic perfect-prognosis methods, conditioned on large-scale atmospheric predictors on a daily basis, for instance multi-site generalised linear models (Chandler, 2020). Another widely used variant is change-factor weather generators: the weather generator parameters are calibrated against present and future climate model simulations, and the climate change signals are then applied to the parameters calibrated to observations. Recent research has mainly focussed on multi-site Richardson type (Markov-chain) weather generators (Keller et al., 2015; Dubrovsky et al., 2019), some explicitly modelling extremes and their spatial dependence (Evin et al., 2018).

10.3.1.3.5 Hybrid approaches and emulators

A wide variety of approaches has been proposed to combine the advantages of different statistical approaches. For instance, to overcome the scale mismatch between climate model output and observations, bias adjustment has been combined with stochastic downscaling (Volosciuk et al., 2017; Lange, 2019) or rescaled analogues (Pierce et al., 2014). Other approaches known as emulators have been developed to emulate an RCM using a statistical model and also applied to a range of driving global models (Déqué et al., 2012; Haas and Pinto, 2012; Walton et al., 2015, 2017; Beusch et al., 2020; Erlandsen et al., 2020).

10.3.2 Types of Model Experiments

The most commonly used model experiments to generate regional climate information are transient simulations. Alternative experiment types serve specific purposes. The role of these experiment types for

ACCEPTED VERSION SUBJECT TO FINAL EDITING

generating regional climate information is assessed in this subsection.

10.3.2.1 Transient simulations and time-slice experiments

Transient simulations intend to represent the evolving climate state of the Earth system (Chapter 4). They are typically based on coupled global model simulations, such as those in the DECK and ScenarioMIP part of CMIP6 covering the period 1850–2100 (Eyring et al., 2016a), and HighResMIP (1950–2050; Haarsma et al., 2016). Global transient climate simulations may be further downscaled by either dynamical or statistical downscaling. Currently available CORDEX RCM simulations (1950–2100) are based on CMIP5 (Gutowski et al., 2016).

In contrast, time-slice experiments are designed to represent only a specific period of time (typically 30 years). They are often run using global and regional models in atmosphere-only mode, forced by SSTs derived either from observations, as AMIP experiments, or from historical simulations and future projections of coupled global models. Compared to transient simulations, they offer advantages in being computationally cheaper (due to the lack of coupled ocean and short duration), which allows for the number of ensemble members (Zhang et al., 2016c), and/or the resolution (Haarsma et al., 2013a; Davini et al., 2017) to be increased. Convection-permitting simulations, both covering the globe or particular regions, are currently conducted for short time slices only (Kendon et al., 2017; Hewitt and Lowe, 2018; Coppola et al., 2020; Pichelli et al., 2021). Another high-resolution time-slice data base is d4PDF (Mizuta et al., 2017; Ishii and Mori, 2020). Experiments covering a limited integration period have been carried out for coupled ocean-atmosphere RCMs (Sein et al., 2015; Zou and Zhou, 2016b, 2017). However, long spin-up periods are required to reach a stable stationary state in the deep ocean that otherwise might lead to invalid projections (Planton et al., 2012; Soto-Navarro et al., 2020).

10.3.2.2 Pseudo-global warming experiments

Results from downscaling experiments often suffer from large-scale circulation biases in the driving GCMs such as misplaced storm tracks (Section 10.3.3.4), while changes in atmospheric circulation are often uncertain owing to both climate response uncertainty (Section 10.3.4.2) and internal variability (Section 10.3.4.3). In a given application, if one can assume that changes in the regional climate are dominated by thermodynamic rather than by circulation changes, so-called pseudo-global warming (PGW) experiments (Schär et al., 1996) may be helpful in mitigating the effects of circulation biases, and to fix the large-scale circulation to present climate. In classical PGW experiments, boundary conditions for the downscaling are taken from reanalysis data, but modified according to the thermodynamic signals of climate change. The boundary conditions thus represent the sequence of observed weather, but with adjusted temperatures, humidity and atmospheric stability. Recent applications of PGW experiments include assessments of climate change in Japan (Adachi et al., 2012; Kawase et al., 2012, 2013), the Los Angeles area (Walton et al., 2015), Hawaii (Zhang et al., 2016a), and the Alps (Keller et al., 2018). Recently, PGW studies have been generalised to modify global model simulations with the objective of separating the drivers of regional climate change, such as the Mediterranean amplification (e.g., Brogli et al., 2019a; Section 10.3.2.3).

Equivalent simulations can be conducted for individual events, thereby allowing for very high resolution. With counterfactual past climate conditions, such simulations can be used for conditional event attribution (Trenberth et al., 2015; Chapter 11), using hypothetical future conditions to generate physical climate storylines of how specific events may manifest in a warmer climate. The approach has been employed to study extreme events that require very high resolution simulations such as tropical cyclones (Lackmann, 2015; Takayabu et al., 2015; Lau et al., 2016; Kanada et al., 2017a; Gutmann et al., 2018; Patricola and Wehner, 2018; Chen et al., 2020a) or convective precipitation events (Pall et al., 2017; Hibino et al., 2018). The range of possible events is broader and has included Korean heat waves (Kim et al., 2018) and monsoon onset in West Africa (Lawal et al., 2016). However, if only individual events are simulated, no immediate conclusions can be derived for changes to the occurrence probability of these events (Otto et al., 2016a; Shepherd, 2016a).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.3.2.3 Sensitivity studies with selected drivers

Sensitivity studies are used to identify the impact of a specific forcing, driver or process on regional climate phenomena and changes and improve the process understanding. The influence of a single external forcing can be assessed with transient historical simulations within two different frameworks (Bindoff et al., 2013; Gillett et al., 2016). The first entails simulations taking prescribed (often observed) changes only in the external forcing of interest, the others being fixed at a constant value (often pre-industrial). The second framework is based on simulations in which all external forcings are applied other than the one of interest. Both approaches may not give the same results since the climate response to a range of forcings is not necessarily equal to the sum of climate responses to individual forcings (Ming and Ramaswamy, 2011; Jones et al., 2013; Schaller et al., 2013; Shiogama et al., 2013; Marvel et al., 2015; Deng et al., 2020).

To study the influence of internal variability, new approaches such as partial coupling simulations are now routinely used since AR5. These are coupled ocean-atmosphere simulations in which the interaction between atmosphere and ocean is only one-way over a specified ocean basin or sub-basin and two-way everywhere else. Different implementations have been used such as SST anomaly Newtonian relaxation at the air-sea interface or prescription of wind-stress anomalies from reanalysis (Kosaka and Xie, 2013, 2016; England et al., 2014; McGregor et al., 2014; Douville et al., 2015; Deser et al., 2017a). Such simulations have been applied to identify the regional impacts of the Pacific Decadal Variability (PDV) and Atlantic Multidecadal Variability (AMV) (Kosaka and Xie, 2013; Watanabe et al., 2014; Delworth et al., 2015; Boer et al., 2016; Ruprich-Robert et al., 2017, 2018).

Nudging experiments have been used to identify the relative roles of dynamic and thermodynamic processes in climate model biases and specific extreme events (Wehrli et al., 2018, 2019). Another related framework is used to evaluate the impact land conditions have on a climate phenomenon in a pair of experiments with one simulation serving as control run, and a perturbed simulation with prescribed land conditions (i.e., soil moisture, leaf area index, or surface albedo) characterizing a specific state of the land surface (i.e., afforestation or deforestation). The difference between the perturbed and control simulations enables a robust assessment of the possible impact of land conditions on events like droughts and heatwaves (Seneviratne et al., 2013; Stegehuis et al., 2015; Hauser et al., 2016, 2017; van den Hurk et al., 2016; Vogel et al., 2017; Rasmijn et al., 2018; Strandberg and Kjellström, 2019).

RCM sensitivity simulations have been used in a similar way to assess the contribution of external forcings and large-scale drivers to projected regional climate change (Nabat et al., 2014; Brogli et al., 2019b, 2019a) and the influence of selected drivers on observed extreme events (Meredith et al., 2015b; Wang et al., 2017a; Ardilouze et al., 2019).

In summary, there is *robust evidence* that sensitivity experiments are key to assessing the influence of different forcings and drivers on regional climate change.

10.3.2.4 Control simulations

In recent years, the role of internal variability in the interpretation of climate projections has become clearer, particularly at the regional scale (Section 10.3.4.3). A considerable fraction of CMIP5 and CMIP6 resources has been invested in generating an ensemble of centennial or multi-centennial control simulations with constant external forcings (Pedro et al., 2016; Rackow et al., 2018). As part of the CMIP6 DECK (Eyring et al., 2016a) pre-industrial control (piControl) simulations have been conducted (Menary et al., 2018). Similarly, control simulations with present-day conditions (pdControl) have been performed to represent internal variability under more recent forcing conditions (Pedro et al., 2016; Williams et al., 2018). Control simulations have been used to study the role of internal variability, teleconnections and many other fundamental aspects of climate models (Wang et al., 2015b; Krishnamurthy and Krishnamurthy, 2016). Control simulations are also used along with large ensembles of historical or scenario simulations to assess

ACCEPTED VERSION SUBJECT TO FINAL EDITING

the characteristics of the regional internal climate variability (Olonscheck and Notz, 2017).

10.3.2.5 Simulations for evaluating downscaling methods

Experiments driven by quasi-perfect boundary conditions or predictors (observations or reanalysis) can be useful to evaluate downscaling performance (Frei et al., 2003; Laprise et al., 2013), including the simulation of observed past trends (Lorenz and Jacob, 2010; Zubler et al., 2011; Nabat et al., 2014; Gutiérrez et al., 2018; Drugé et al., 2019; Bozkurt et al., 2020) and the added value of downscaling compared to the reanalysis fields (Section 10.3.3.2). Although the reanalysis model itself can introduce biases especially for non-assimilated variables (such as precipitation) it is assumed that in such a setting, discrepancies between the modelled and observed climate arise mostly from errors in the downscaling method (Laprise et al., 2013) or internal climate variability generated by the downscaling method (Böhnisch et al., 2020; Ehmele et al., 2020). Since AR5, reanalysis-driven RCMs have been extensively evaluated for many regions, especially in the CORDEX framework (see region specific examples in the Atlas).

Over Europe, the VALUE initiative assessed statistical downscaling for marginal, temporal, and spatial aspects of temperature and precipitation including extremes, and performed a process-based evaluation of specific climatic phenomena (Gutiérrez et al., 2018; Maraun et al., 2018). Alternatively, statistical downscaling can be evaluated in so-called perfect model or pseudo-reality simulations (Charles et al., 1999), where a high-resolution climate model simulation is used as a proxy for a hypothetical present and future realities. A statistical downscaling model is first calibrated with this pseudo present-day climate and, subsequently, assessed whether it correctly reproduces the pseudo-future conditions (Dixon et al., 2016).

10.3.3 Model Performance and Added Value in Simulating and Projecting Regional Climate

Assessing model performance is a prerequisite for building confidence in regional climate projections. This subsection assesses the performance of different model types at simulating regional climate and climate change. The subsection builds on the assessment of global model performance in Chapter 3, and complements the model assessment in Chapter 8, which focuses on the water cycle, and the Atlas.

[START FIGURE 10.6 HERE]

Figure 10.6: Illustration of some model biases in simulations performed with dynamical models. (a) Top row: Mean summer (June to August) near-surface air temperature (in °C) over the Mediterranean area in Berkeley Earth and respective mean bias for five multi-model historical experiments with GCMs (CMIP5, CMIP6 and HighResMIP) and RCMs (CORDEX EUR-44 and EUR-11) averaged between 1986–2005. Bottom row: Box-and-whisker plot shows spread of the 20 annual mean summer surface air temperature averaged over land areas in the western Mediterranean region (33°N–45°N, 10°W–10°E, black quadrilateral in the first panel of the top row) for a set of references and single model runs of the five multi-model experiments (one simulation per model) between 1986–2005. Additional observation and reanalysis data included in the bottom row are CRU TS, HadCRUT4, HadCRUT5, E-OBS, WFDE5, ERA5, ERA-Interim, CERA-20C, JRA-25, JRA-55, CFSR, MERRA2, MERRA. Berkeley Earth is shown in the first box to the left. (b) as (a) but for precipitation rate (mm day^{-1}) and showing CRU TS in the first panel of the top row. Biases of the five multi-model experiments are shown with respect to CRU TS. Additional observation and reanalysis data included in the bottom row are GPCC, REGEN, E-OBS, GHCN, WFDE5, CFSR, ERA-Interim, ERA5, JRA-55, MERRA2, MERRA. CRU TS is shown in the first box to the left. All box-and-whisker plots show the median (line), and the interquartile range (IQR = Q3–Q1, box), with top whiskers extending to the last data less than Q3+1.5×IQR and analogously for bottom whiskers. Data outside the whiskers range appear as flyers (circles). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.6 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

While the ability of global models to simulate large-scale indicators of climate change has improved since AR5 (Chapter 3), the simulation of regional climate and climate change poses an additional challenge. Users demand regional climate projections for decision making and have high expectations regarding accuracy and resolution (Rössler et al., 2019a), but some scientists consider such projections still a matter of basic research (Hewitson et al., 2014a). For instance, large-scale circulation biases or the misrepresentation of regional topography as well as regional phenomena and feedbacks are very relevant (Hall, 2014; Maraun and Widmann, 2018b). New global model ensembles such as CMIP6 (Eyring et al., 2016a), HighResMIP (Haarsma et al., 2016) or, at the regional scale, the convection permitting simulations from the CORDEX Flagship Pilot Study (FPS) on convective phenomena (Coppola et al., 2020) have the potential to substantially improve the basis for generating regional climate information, yet uncertainties and (often unresolved) contradictions between model projections at the regional scale can be substantial (Fernández et al., 2019).

Figure 10.6 shows the mean summer temperature and precipitation biases of several state-of-the-art climate model ensembles for the western Mediterranean. It additionally illustrates the role of observational uncertainty for model evaluation (Section 10.2), where observations display differences that can be substantial. Model performance varies strongly from model to model, but also between ensembles. These biases are an expression of model error that leads to misrepresented phenomena and processes, and thus limit the confidence in future projections of regional climate. The focus of this subsection is therefore to evaluate the representation of relevant regional scale phenomena for representing regional climate.

10.3.3.1 Evaluation diagnostics

Since AR5, model evaluation has made use of a broad combination of diagnostics (Colette et al., 2012; Kotlarski et al., 2014; Eyring et al., 2016b; Gleckler et al., 2016; Ivanov et al., 2017, 2018; Vautard et al., 2020), ranging from long-term means to indices of extreme events (Zhang et al., 2011; Sillmann et al., 2013) or a combination of these (Dittus et al., 2016). This evaluation has shown that global models have pervasive biases in some aspects of their large-scale behaviour (Section 1.5.3.1, Chapter 3). More complex diagnostics are used to characterize specific meteorological phenomena (Sprenger et al., 2017), such as feedbacks in the El Niño-Southern Oscillation (ENSO; Bellenger et al., 2014), Madden-Julian Oscillation (MJO) characteristics (Ahn et al., 2017; Benedict et al., 2014; Jiang et al., 2015; Kim et al., 2015), extra-tropical modes of variability (Lee et al., 2019), cyclone tracking (Neu et al., 2013; Flaounas et al., 2018), front detection (Hope et al., 2014; Schemm et al., 2015), thunderstorm environment parameters (Bukovsky et al., 2017), African easterly waves (McCrary et al., 2014; Martin and Thorncroft, 2015), land-atmosphere coupling (Spennemann and Saulo, 2015; Santanello et al., 2018), and sea-atmosphere coupling (Bellenger et al., 2014; Mayer et al., 2017).

New diagnostics for multivariate dependencies are needed to characterize compound events (Section 11.8; Hobaek Haff et al., 2015; Wahl et al., 2015; Sippel et al., 2016, 2017; Tencer et al., 2016; Bevacqua et al., 2017; Careto et al., 2018; Zscheischler et al., 2018b). However, their success depends on the availability of adequate observational data (Section 10.2.2). Multivariate dependencies discovered in compound events can also be used for designing and evaluating multivariate bias adjustment and statistical downscaling. Process-based diagnostics are useful for identifying the cause of model errors, although it is not always possible to associate a systematic error with a specific cause (Eyring et al., 2019). AR5 discussed two approaches of process-based evaluation: 1) the isolation of physical components or parameterizations by dedicated experiments (Section 10.3.2.4) and 2) diagnostics conditioned on relevant regimes, usually synoptic-scale weather patterns. The regime-based approach has been used with both global models (e.g., Barton et al., 2012; Catto et al., 2015; Taylor et al., 2019) and RCMs (Endris et al., 2016; Bukovsky et al., 2017; Whan and Zwiers, 2017; Pinto et al., 2018), but also with perfect prognosis and bias adjustment methods (Marteau et al., 2015; Addor et al., 2016; Beranová and Kyselý, 2016; Soares and Cardoso, 2018; Soares et al., 2019b).

Recent studies highlight the importance of user-defined or user-relevant diagnostics for model evaluation (Maraun et al., 2015; Rhoades et al., 2018; Rössler et al., 2019b; Nissan et al., 2020). Diagnostics have been

ACCEPTED VERSION SUBJECT TO FINAL EDITING

used to assess the performance of climate models to produce useful input data for impact models as in the comparison between RCMs and convection-permitting models to capture flood generating precipitation events in the Alps (Reszler et al., 2018). Alternatively, the observed impact can be compared to that simulated by an impact model that uses input from both observations and climate models. This approach has been used to evaluate the influence of statistical downscaling and bias adjustment on hydrological (Rojas et al., 2011; Chen et al., 2012b; Gutiérrez et al., 2019; Rössler et al., 2019b), agricultural (Ruiz-Ramos et al., 2016; Galmarini et al., 2019), forest and wildfire (Abatzoglou and Brown, 2012; Migliavacca et al., 2013) (Bedia et al., 2013), snow depth (Verfaillie et al., 2017), and regional ocean modelling (e.g., Macias et al., 2018).

There is *high confidence* that to assess whether a climate model realistically simulates required aspects of present-day regional climate, and to increase confidence of future projections of these aspects, evaluation needs to be based on diagnostics taking into account multiple variables and process-understanding.

10.3.3.2 Model improvement and added value

Obtaining regional information from global simulations may involve a range of different methods (Section 10.3.1). An approach with higher complexity or resolution is useful if it adds further, useful information to that of a reference model. Section 10.5 discusses the set of considerations that determine if the information is useful. This further useful information is often referred to as added value and is a function of variables, processes, and the temporal and spatial scales targeted taking into account the needs of specific users (Di Luca et al., 2012; Ekström et al., 2015; Giorgi and Gutowski, 2015; Torma et al., 2015; Rummukainen, 2016; Falco et al., 2018). There is no common definition of added value, but here it is considered a characteristic that arises when one methodology gives further value to what another methodology yields.

Downscaling is expected to improve the representation of a region's climate compared to the driving GCM (Di Luca et al., 2015). Arguably, there should be a clear physical reason for the improvement, which is applicable to the evaluation of added value in downscaled projections (Giorgi et al., 2016). The added value depends on the region, season, and governing physical processes (Lenz et al., 2017; Schaaf and Feser, 2018). Thus, added value of downscaling GCM simulations is most likely where regional- and local-scale processes play an important role in a region's climate, for example in complex or heterogeneous terrain such as mountains (Lee and Hong, 2014; Prein et al., 2016a), urban areas (Argüeso et al., 2014), along coastlines (Feser et al., 2011; Herrmann et al., 2011; Bozkurt et al., 2019), or where convective processes are important (Prein et al., 2015). Examples of model improvements and added value are given in the following subsections and the Atlas.

A first step in determining added value in downscaling is to analyse whether the downscaling procedure gives detail on spatial or temporal scales not well-resolved by a GCM, thus potentially representing climatic features missing in the GCM. This added detail, referred to as potential added value (PAV; Di Luca et al., 2012), is insufficient for demonstrating added value in downscaling (Takayabu et al., 2016), but lack of PAV indicates that the downscaling method lacks usefulness. Added value is not guaranteed simply by producing model output at finer resolution. It depends on several factors, such as the simulation setup and the specific climatic variables analysed (Di Luca et al., 2012; Hong and Kanamitsu, 2014; Xue et al., 2014). A variety of performance measures are needed to assess added value (Section 10.3.3.1; Di Luca et al., 2016; Wilks, 2016; Ivanov et al., 2017, 2018; Soares and Cardoso, 2018).

A further challenge, especially at increasingly higher resolutions, is that adequate observational data may not be available to assess added value (Section 10.2, e.g., Di Luca et al., 2016; Zittis et al., 2017; Bozkurt et al., 2019). This implies a need for additional efforts to obtain, catalogue and quality-control higher resolution observational (or observation-based) data sets (Thorne et al., 2017; Section 10.2). Univariate demonstration of added value is necessary, but may be insufficient, as better agreement with observations in the downscaled variable may be a consequence of compensating errors that are not guaranteed to compensate similarly as climate changes. Multivariate analysis of added value is better able to demonstrate physical consistency between observed and simulated behaviour (Prein et al., 2013a; Meredith et al., 2015a; Reboita et al., 2018).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.3.3.3 Performance at simulating large-scale phenomena and teleconnections relevant for regional climate

Regional climate is often controlled by large-scale weather phenomena, modes of variability and teleconnections (e.g., Sections 2.3 and 2.4, Annex IV). In particular extreme events are often caused by specific, in some cases persistent, circulation patterns (Sections 11.3–11.7). It is therefore important for climate models to reasonably represent not only continental, but also regional climate and its variability for such extremes. As explained in Section 3.3.3, standard resolution GCMs can suffer biases in the location, occurrence frequency or intensity of large-scale phenomena, such that statements about a specific regional climate and its change can be highly uncertain (Hall, 2014). RCMs have difficulties improving especially large-scale circulation biases, although some successful examples exist. But due to their enhanced representation of complex topography and coastlines, RCMs may add value to simulating the regional expression of teleconnections. Bias adjustment cannot mitigate fundamental misrepresentations of the large-scale atmospheric circulation (Maraun et al., 2017, Cross-Chapter Box 10.2). This subsection illustrates the relevance of large-scale circulation biases for regional climate assessments with selected examples from the mid-to-high latitudes and tropics.

10.3.3.3.1 Mid-to-high latitude atmospheric variability phenomena: blocking and extratropical cyclones

Major large-scale meteorological phenomena for mid-to-high latitude mean and extreme climate include atmospheric blocking and extratropical cyclones (Section 2.3.1.4). Atmospheric blocking is characterized by a quasi-stationary long-lasting, high pressure system that blocks and diverts the movement of synoptic cyclones (Woollings et al., 2018). In regions where blocking occurs, it is known to lead to cold conditions in winter and warmth and drought during summer, defining the seasonal regional climate in certain years (Sousa et al., 2017, 2018b). Extratropical cyclones are storm systems that propagate preferentially in confined storm-track regions, characterized by large eddy-kinetic energy, heat and momentum transports that shape regional weather at mid-to-high latitudes (Shaw et al., 2016). Given their importance in shaping mean and extreme regional climate (Sections 3.3.3.3, 11.3 and 11.4), an accurate representation of blocking and extratropical cyclones in global and regional climate models is needed to better understand regional climate variability and extremes as well as to project future changes (Section 11.7.2; Grotjahn et al., 2016; Mitchell et al., 2017; Rohrer et al., 2018; Huguenin et al., 2020). An overview of CMIP5 and CMIP6 model performance in simulating blocking and extratropical cyclones is given in Section 3.3.3.3. CMIP6 models still suffer from long-standing blocking biases identified in previous generations of models. However, blocking location has improved compared to CMIP5, while comparable performance is seen for blocking frequency and persistence (Figure 10.7). Increasing horizontal model resolution to about 20 km in the HighResMIP experiments improves the representation of blocking frequency and its spatial pattern in most models, but no clear effect could be shown for blocking persistence. Biases associated with these two phenomena are highly region- and season-dependent and their amplitudes vary among CMIP models (Drouard and Woollings, 2018; Schaller et al., 2018; Woollings et al., 2018; Harvey et al., 2020; Schiemann et al., 2020).

[START FIGURE 10.7 HERE]

Figure 10.7: Northern-Hemisphere blocking performance in historical coupled simulations for different multi-model ensembles. CMIP5/6: CMIP5 and CMIP6 DECK historical simulations, 1950-2005, LC/HC: Low/High-resolution simulations from the PRIMAVERA project, 1950–2014 following the hist-1950 experiment of the CMIP6 HighResMIP Protocol, (Haarsma et al., 2016). (top) blocking frequency, i.e. fraction of blocked days; (middle) root-mean-squared error in blocking frequency; (bottom) 90th percentile of blocking persistence, aggregated over an Atlantic domain (left, ATL: 90ºW–90ºE, 50º–75ºN) and a Pacific domain (right, PAC: 90ºE–270ºE, 50º–75ºN). Results are for boreal winter (DJF) and summer (JJA). Box-and-whisker plots for CMIP5/6 follow the methodology used in Figure 10.6 and show median (line), mean (triangle), and interquartile range (box) across 29 models for each ensemble. The reference estimate (ERA, asterisk) is from a 50-year reanalysis dataset that merged ERA-40 (1962–

ACCEPTED VERSION SUBJECT TO FINAL EDITING

1978) and ERA-Interim (1979–2011) reanalyses. An estimate of internal variability for each metric (IV) is shown as a box-and-whisker plot over the asterisk and is obtained from a single-model ensemble (ECMWF-IFS high-resolution hist-1950 experiment, 6 x 65 years). For details on the methodology see (Schiemann et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.7 HERE]

RCMs have a very limited ability to reduce large-scale circulation errors of the driving GCM (Hall, 2014). In a study of five ERA-Interim-driven RCMs, Jury et al. (2018) showed that RCMs typically simulate fewer blocking events over Europe than are present in the driving data, irrespective of the RCM horizontal resolution. Based on a simple blocking bias-decomposition method, they suggest that blocking frequency biases can contribute to the RCM mean surface biases. Over some large domains, reanalysis-driven RCMs can significantly improve the representation of storm characteristics compared to the driving reanalysis near regions with complex orography and/or large water masses (Poan et al., 2018). However, this is not necessarily true if the domain is large enough because the RCM and its biases will then control the circulation leading to a biased performance with regard to storm characteristics (Pontoppidan et al., 2019). An ensemble of 12 RCMs with and without air-sea coupling reasonably reproduced the climatology of Mediterranean cyclones, and air-sea coupling had a rather weak impact (Flaounas et al. 2018). Over the Gulf Stream, however, air-sea coupling played an important role in representing cyclone development (Vries et al., 2019). Sánchez-Gómez and Somot (2018) showed that the effect of RCM internal variability on density of cyclone tracks is very significant and larger than for other variables such as precipitation. It is larger in summer than in winter, in particular over the Iberian Peninsula, northern Africa and the eastern Mediterranean, which are regions of enhanced cyclogenesis during the warm season.

Biases in the representation of large-scale atmospheric circulation can result in biased representation of regional climate. While the connection between large-scale and regional biases is in principle obvious, given the strong control of regional climate by large-scale phenomena, research on this connection is still limited. Munday and Washington (2018) relate CMIP5 model rainfall biases over South Africa to anomalous low-level moisture transport across high-topography due to upstream wind biases and inaccurate representation of unresolved orographic drag effects. Addor et al. (2016) show that the overestimated frequency of westerly synoptic situations was a significant contributor to the wet bias in several RCMs in winter over Switzerland. Pepler et al. (2014, 2016) suggest that better capturing westerly-driven synoptic systems such as cold fronts and cut-off lows in climate models could be key in simulating the observed pattern correlation between rainfall and zonal wind in southern southeast Australia. Cannon (2020) shows global improvement in performance going from CMIP5 to CMIP6 for both frequency and persistence of circulation types.

The robust quantification of the influence of atmospheric circulation errors on regional climate remains a challenge as many parameterized processes such as cloud radiative effects and soil moisture or snow feedbacks can also contribute and interact with the circulation errors. Atmospheric nudging experiments where the simulated circulation is constrained to be close to that observed have been used to separate the circulation effect from other contributions to regional climate biases (Wehrli et al., 2018). The nudging approach requires detailed and careful implementation in order to limit detrimental effects due to the added tendency term in the model equations (Zhang et al., 2014; Lin et al., 2016). Based on single-model experiments, Wehrli et al. (2018) show that the circulation-induced biases are often not the main contributors to mean and extreme temperature and precipitation biases for many regions and seasons.

There is *high confidence* that atmospheric circulation biases can deteriorate the model representation of regional land surface climate. Assessing the relative contributions of atmospheric circulation and other sources of bias remains a challenge due to the strong coupling between the atmosphere and other components of the climate system, including the land surface.

10.3.3.3.2 Tropical phenomena: ENSO teleconnections

Model performance in simulating ENSO characteristics, including ENSO spatial pattern, frequency,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

asymmetry between warm and cold events, and diversity, is assessed in Chapter 3 (Section 3.7.3). The ability of the recent generation of GCMs and RCMs to adequately simulate ENSO-related teleconnections is reviewed here along with relevant methodological issues (see also Annex IV2.3.2, Figure 3.38 and Section 3.7.3).

Langenbrunner and Neelin (2013) show that there is little improvement in CMIP5 relative to CMIP3 in amplitude and spatial patterns of the ENSO influence on boreal winter precipitation (spatial pattern correlations against observations are typically less than 0.5). However, the CMIP5 ensemble accurately represents the amplitude of the precipitation response in regions where observed teleconnections are strong. (Garcia-Villada et al., 2020) found a decline in performance of the representation of simulated ENSO teleconnection patterns for model experiments with fewer observational constraints. They also show that ENSO warm phase (El Niño) teleconnections are better represented than those for the cold phase (La Niña). Individual CMIP5 and CMIP6 models show a good ability to represent the observed teleconnections at aggregated spatial scales (Power and Delage, 2018; Section 3.7.3 and Figure 3.38). The evaluation of the atmospheric dynamical linkages is also an important part of the assessment. Hurwitz et al. (2014) showed that CMIP5 models broadly simulate the expected (as seen in the MERRA reanalysis) upper-tropospheric responses to central equatorial Pacific or eastern equatorial Pacific ENSO events in boreal autumn and winter. CMIP5 models also simulate the correct sign of the Arctic stratospheric response, consisting of polar vortex weakening during eastern and central Pacific Niño events and vortex strengthening during both types of La Niña events. In contrast, most CMIP5 models do not capture the observed weakening of the Southern Hemisphere polar vortex in response to central Pacific ENSO events (Brown et al., 2013).

In RCMs, the effects of tropical large-scale modes and teleconnections are inherited through the boundary conditions and influenced by the size of the numerical domain. Done et al. (2015) and Erfanian and Wang (2018) claim that large domains that include source oceanic regions are required to capture the remote influence of teleconnections, although, without spectral nudging, this can lead to biased synoptic-scale patterns (Prein et al., 2019). RCMs generally reproduce the regional precipitation responses to ENSO, and can sometimes even improve the representation of these teleconnections compared to the driving reanalysis (Endris et al., 2013; Fita et al., 2017), but the overall performance may depend both on the driving reanalysis or GCM (Endris et al., 2016; Chandrasa and Montenegro, 2019) and on the chosen RCMs (Whan and Zwiers, 2017).

New studies since AR5 have shown that model performance assessment regarding ENSO teleconnections remains a difficult challenge due to the different types of ENSO and model errors in ENSO spatial patterns, as well as the strong influence of atmospheric internal variability at mid-to-high latitudes (Coats et al., 2013; Polade et al., 2013; Capotondi et al., 2015; Deser et al., 2017; Tedeschi and Collins, 2017; Garcia-Villada et al., 2020). Another difficulty comes from the non-stationary aspects of teleconnections in both observations and models, raising methodological questions on how best to compare a given model with another model or observations (Herein et al., 2017; Perry et al., 2017; O'Reilly, 2018; O'Reilly et al., 2019; Abram et al., 2020).

There is *robust evidence* that an accurate representation of both atmospheric circulation and SST variability are key factors for the realistic representation of ENSO teleconnections in climate models. A robust and thorough evaluation of model performance regarding ENSO teleconnections is a challenging task with many methodological issues related to asymmetry between the warm and cold phases, non-stationarity and time-varying interaction between the Pacific and other ocean basins, signal-to-noise issues in the mid-latitudes and observational uncertainties, particularly for precipitation (Section 10.2.2.3).

10.3.3.4 Performance at simulating regional phenomena and processes

Regional climate is shaped by a wide range of weather phenomena occurring at scales from about 2,000 km to 2 km (Figure 10.3). These modulate the influence of large-scale atmospheric phenomena and create the characteristic and potentially severe weather conditions. The climate in different regions will be affected by different mesoscale phenomena, of which several may be relevant. A skilful representation of these

ACCEPTED VERSION SUBJECT TO FINAL EDITING

phenomena is a necessary condition for providing credible and relevant climate information for a given region and application. Therefore, it is important to understand the strengths and weaknesses of different model types in simulating these phenomena. The performance of different dynamical climate model types to simulate a selection of relevant mesoscale weather phenomena is assessed here.

10.3.3.4.1 Convection including tropical cyclones

Convection is the process of vertical mixing due to atmospheric instability. Deep moist convection is associated with thunderstorms and severe weather such as heavy precipitation and strong wind gusts. Convection may occur in single locations, in spatially extended severe events such as supercells, and organised into larger mesoscale convective systems such as squall lines or tropical cyclones, and embedded in fronts (see below). Shallow and deep convection are not explicitly simulated but parameterized in standard global and regional models. In consequence, these models suffer from several biases. AR5 has stated that many CMIP3 and CMIP5 models simulate the peak in the diurnal cycle of precipitation too early, but increasing resolution and better parameterisations help to mitigate this problem (Flato et al., 2014). Similar issues arise for RCMs with parameterised deep convection (Prein et al., 2015), which also tend to overestimate high cloud cover (Langhans et al., 2013; Keller et al., 2016).

Non-hydrostatic RCMs at convection-permitting resolution (4 km and finer) improve features such as the initiation and diurnal cycle of convection (Zhu et al., 2012; Prein et al., 2013a, 2013b; Fosser et al., 2015; Berthou et al., 2018a; Stratton et al., 2018; Sugimoto et al., 2018; Finney et al., 2019; Ban et al., 2021; Pichelli et al., 2021), the triggering of convection by orographic lifting (Langhans et al., 2013; Fosser et al., 2015), and maximum vertical wind speeds in convective cells (Meredith et al., 2015a). Also spatial patterns of precipitation (Prein et al., 2013a, 2013b; Stratton et al., 2018), precipitation intensities (Prein et al., 2015; Fumière et al., 2019; Ban et al., 2021; Pichelli et al., 2021), the scaling of precipitation with temperature (Ban et al., 2014), cloud cover (Böhme et al., 2011; Langhans et al., 2013) and its resultant radiative effects (Stratton et al., 2018), as well as the annual cycle of tropical convection (Hart et al., 2018) are improved. Phenomena such as supercells, mesoscale convective systems, or the local weather associated with squall lines are not captured by global models and standard RCMs. Convection-permitting RCM simulations, however, have been shown to realistically simulate supercells (Trapp et al., 2011), mesoscale convective systems, their life cycle and motion (Prein et al., 2017; Crook et al., 2019), and heavy precipitation associated with a squall line (Kendon et al., 2014). There is *high confidence* that simulations at convection permitting resolution add value to the representation of deep convection and related phenomena.

Convection is the key ingredient of tropical cyclones. An intercomparison of high-resolution AGCM simulations (Shaevitz et al., 2014) showed that tropical cyclone intensities appeared to be better represented with increasing model resolution. Takayabu et al. (2015) have compared simulations of typhoon Haiyan at different resolutions ranging from 20 km to 1 km (Figure 10.8). While the eyewall structure in the precipitation pattern was strongly smoothed in the coarse resolution simulations, it was well resolved at the highest resolution. Gentry and Lackmann (2010) found similar improvements in simulating hurricane Ivan for horizontal resolutions between 8 km and 1 km. High-resolution coupled ocean-atmosphere simulations improve the representation of the radial structure of core convection and thereby the rapid intensification of the cyclone (Kanada et al., 2017b). There is *high confidence* that convection-permitting resolution is required to realistically simulate the three-dimensional structure of tropical cyclones.

Initial studies with convection-permitting GCMs suggests that improvements in representing convection, as described for RCMs above, have a positive impact on the tropical and extra-tropical atmospheric circulation and, thus, regional climate (Satoh et al., 2019; Stevens et al., 2019; see also Section 8.5.1.2 and Chapter 7). Computational constraints currently limit these simulations to a length of few months only, such that they cannot yet be used for routine climate change studies.

10.3.3.4.2 Mountain wind systems

Mountain slope and valley winds are localised thermally generated diurnal circulations that have a strong influence on temperature and precipitation patterns in mountain regions. During the day, heating of mountain slopes induces upslope winds; during the night this circulation reverses. This phenomenon is not realistically represented by global models and coarse-resolution RCMs. RCM simulations at 4 km resolution showed good skill in simulating the diurnal cycle of temperature and wind on days of weak synoptic forcing in the Rocky Mountains (Letcher and Minder, 2017) as well as in simulating the mountain-plain wind circulation over the Tianshan mountains in Central Asia (Cai et al. 2019), while in the Alps, a 1 km resolution has been required (Zängl, 2004).

Föhn winds are synoptically-driven winds across a mountain range that are warm and dry due to adiabatic warming in the downwind side. In an RCM study for the Japanese Alps, Ishizaki and Takayabu (2009) found that at least 10 km resolution was required to realistically simulate the basic characteristics of Föhn events.

Synoptically-forced winds may be channelled and accelerated in long valleys. For instance, the Tramontana, Mistral and Bora are northerly winds blowing down-valley from central France and the Balkans into the Mediterranean (Flaounas et al., 2013). In winter, these winds may cause severe cold air outbreaks along the coast. Flaounas et al. (2013) have shown that a GCM with a horizontal resolution of roughly 3.75° longitude/1.875° latitude (roughly 400 km x 200 km depending on latitude) is unable to reproduce these winds because of the coarse representation of orography. 50-km RCM simulations did not realistically represent the Mistral (Obermann et al., 2018) and Bora winds (Belušić et al., 2018), but simulations at 12 km added substantial value. Similarly, Cholette et al. (2015) found that a 30-km RCM resolution was not sufficient to adequately simulate the channelling of winds in the St Lawrence River Valley in eastern Canada, whereas a 10 km resolution was.

There is *high confidence* that climate models with resolutions of around 10 km or finer are necessary for realistically simulating mountain wind systems such as slope and valley winds and the channelling of winds in valleys.

10.3.3.4.3 Coastal winds and lake effects

Simulating coastal climates and the influence of big lakes are a modelling challenge, due to the complex coastlines, the different heat capacities of land and water, the resulting wind system, and differential evaporation. The AR5 concluded that RCMs can add value to the simulation of coastal climates.

Summer coastal low-level jets off the mid-latitude western continental coasts are forced by the semi-permanent subtropical anticyclones, inland thermal lows, strong across-shore temperature contrasts in upwelling regions, and high coastal topography. They are important factors in shaping regional climate by, for instance, preventing onshore advection of humidity and thereby causing aridity in the Iberian Peninsula (Soares et al., 2014), or by transporting moisture towards precipitating regions as in the North American monsoon (Bukovsky et al., 2013).

Reanalyses and most global models do not well resolve the details of coastal low-level jets (Bukovsky et al., 2013; Soares et al., 2014), but they are still able to represent annual and diurnal cycles and interannual variability (Cardoso et al., 2016; Lima et al., 2019). Bukovsky et al. (2013) found RCM simulations at a 50 km resolution to improve the representation of the coastal low-level jet in the Gulf of California and the

ACCEPTED VERSION SUBJECT TO FINAL EDITING

associated precipitation pattern compared to the driving global models. Lucas-Picher et al. (2017) find indirect evidence via precipitation patterns that 12 km simulations further improve the representation. Soares et al. (2014) demonstrated that an 8-km resolution RCM simulated a realistic three-dimensional structure of the Iberian coastal low-level jet, and the surface winds compare well with observations. Lucas-Picher et al. (2017) showed that a 0.44°-resolution RCM underestimated winds along the Canadian east coast, whereas a 0.11°-resolution version simulated more realistic 10-metre wind speed. Also, the Etesian winds in the Aegean Sea were realistically simulated by 12 km-resolution RCMs (Dafka et al., 2018).

A particularly relevant coastal phenomenon is the sea breeze, which is caused by the differential heating of water and land during the diurnal cycle and typically reaches several tens of kilometres inland. Reanalyses and global models have too coarse a resolution to realistically represent this phenomenon, such that they typically underestimate precipitation over islands and misrepresent its diurnal cycle (Lucas-Picher et al., 2017). RCMs improve the representation of sea breezes and thereby precipitation in coastal areas and islands. Over Cuba and Florida only a 12 km-resolution RCM is able to realistically simulate the inland propagation of precipitation during the course of the day (Lucas-Picher et al., 2017). RCM simulations at 20 km horizontal resolution realistically represented the sea breeze circulation in the Mediterranean Gulf of Lions including the intensity, direction and inward propagation (Drobinski et al., 2018). Even though a coupled ocean-atmosphere simulation improved the representation of diurnal SST variations, the sea breeze representation itself was not improved.

Big lakes modify the downwind climate. In particular during winter they are relatively warm compared to the surrounding land, provide moisture, destabilize the passing air column and produce convective systems. The increase in friction when moving air reaches land causes convergence and uplift, and may trigger precipitation. Gula and Peltier (2012) found that a state-of-the-art GCM does not realistically simulate these effects over the North American Great Lakes, but a 10 km RCM better represents them and thereby simulates realistic downwind precipitation patterns, in particular enhanced snowfall during the winter season. Similar results were found by Wright et al. (2013), Notaro et al. (2015) and Lucas-Picher et al. (2017). In a convection permitting simulation of the Lake Victoria region, a too strong nocturnal land-breeze resulted in unrealistically high precipitation (Finney et al., 2019).

There is *high confidence* that climate models with sufficiently high resolution are necessary for realistically simulating lake and coastal weather including coastal low-level jets, lake and sea breezes, as well as lake effects on rainfall and snow.

In regions like Fenno-Scandinavia or central-eastern Canada, very large fractions of land are covered by small and medium sized lakes. Other regions have fewer but larger lakes, such as central-eastern Africa, the eastern border between the US and Canada, and central Asia. In these regions it has been considered essential to include a lake model in an RCM to realistically represent regional temperatures (Deng et al., 2013; Mallard et al., 2014; Pietikäinen et al., 2018; Samuelsson et al., 2010; Thiery et al., 2015), as well as remote effects (Spero et al., 2016). The most common approach in RCMs is the two-layer lake model, including a lake-ice model, with parameterized vertical temperature profiles (Mironov et al., 2010; Golosov et al., 2018). For the Caspian Sea, it is found that a three dimensional ocean model simulated the SST fields better than a one dimensional lake model when coupled to the same RCM (Turuncoglu et al., 2013).

There is *medium evidence* and *high agreement* that it is important to include interactive lake models in RCMs to improve the simulation of regional temperature, in particular in seasonally ice-covered areas with large fractions of lakes. There is *medium evidence* of the local influence of lakes on snow and rainfall as well as the importance of including lakes in regional climate simulations.

10.3.3.4.4 Fronts

Weather fronts are two-dimensional surfaces separating air masses of different characteristics and are a key element of mid-latitude cyclones. In particular cold fronts are regions of relatively strong uplift and hence often associated with severe weather (e.g., Schemm et al., 2016). Stationary or slowly moving fronts may cause extended heavy precipitation. The evaluation of how climate models represent fronts, however,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

remains limited. Catto et al. (2014) found in both ERA-Interim and CMIP5 models that frontal frequency and strength were realistically simulated, albeit with some biases in the location. Follow-up investigations, for boreal and austral winter (Catto et al., 2015) found frontal precipitation frequency to be too high and the intensity too low, but these compensating biases resulted in only a small total precipitation bias. Blázquez and Solman (2018) found similar results for Southern Hemisphere winter, and also showed that CMIP5 models typically overestimate the fraction of frontal precipitation compared to total precipitation. As for the reference, the ERA-Interim reanalysis misrepresents conditional symmetric instability associated with fronts, and the corresponding precipitation (Glinton et al., 2017). Only a few studies evaluating fronts in RCMs have been conducted. Kawazoe and Gutowski (2013) diagnosed strong temperature gradients associated with extreme winter precipitation in the North American Regional Climate Change Assessment Program (NARCCAP) RCM ensemble (Mearns et al., 2012) and found the models agreed well with gradients in a reanalysis. De Jesus et al. (2016) diagnosed the representations of cold fronts over southern Brazil in two RCMs, finding that they were only underestimated by about 5% across the year, but in one RCM, summer cold fronts were underestimated by 17%. An RCM-based reanalysis suggests that high-resolution RCM simulations improve the representation of orographic influences on fronts (Jenkner et al., 2009).

10.3.3.5 Performance at simulating regional feedbacks

Both the SRCCL (Jia et al., 2019) and SROCC (Hock et al., 2019) highlight the weaknesses of climate models at simulating atmosphere-surface feedbacks. The performance at simulating some of these feedbacks is assessed below (climate feedbacks in urban areas are discussed in Box 10.3).

The snow-albedo feedback contributes to enhanced warming at high elevations (Pepin et al., 2015; Section 8.5). Global models often do not simulate it realistically due to their misrepresentation of orography in complex terrain (Hall, 2014; Walton et al., 2015). The elevation dependence of historical warming, which is partly caused by the snow-albedo effect, is realistically represented across Europe by the ENSEMBLES RCMs (Kotlarski et al., 2015). Some EURO-CORDEX RCMs simulate a springtime snow-albedo feedback close to that observed, whereas others considerably overestimate it (Winter et al., 2017). In a multi-physics ensemble RCM experiment, the cold bias in northeastern Europe is amplified by the albedo feedback (García-Díez et al., 2015). For the Rocky Mountains, RCM simulations generally reproduce the observed spatial and seasonal variability in snow cover, but strongly overestimate the snow albedo (Minder et al., 2016). There is *high confidence* (*medium evidence* and *high agreement*) that RCMs considerably improve the representation of the snow albedo effect in complex terrain.

Soil-moisture feedbacks influence changes in both temperature and precipitation. More than 30% of CMIP5 models overestimate the influence of preceding precipitation (a proxy for soil moisture) on temperature extremes in Europe and the USA (Donat et al., 2018), and many CMIP5 models simulate an unrealistic influence of evaporation on temperature extremes for wet regions in Europe and the US (Ukkola et al., 2018). RCMs were found to realistically simulate the correlation between latent and sensible heat fluxes and temperature (coupling strength) over Africa (Knist et al., 2017; Careto et al., 2018) and in Northern and Southern Europe, but to overestimate it in Central Europe (Knist et al., 2017). Land-surface models driven by global reanalysis agreed relatively well with observations. However, the coupling strength varied strongly across models at the regional scale, and a realistic partitioning of the incoming radiation into latent and sensible heat fluxes did not necessarily result in a realistic soil moisture-temperature coupling (Gevaert et al., 2018; Boé et al., 2020a).

Evaluating the representation of soil moisture-precipitation feedbacks in climate models is challenging as different processes may induce feedbacks including moisture recycling, boundary-layer dynamics and mesoscale circulation. Moreover, the effects of soil-moisture on precipitation may be region and scale dependent and may even change sign depending on the strength of the background flow (Taylor et al., 2013; Froidevaux et al., 2014; Guillod et al., 2015; Larsen et al., 2016; Tuttle and Salvucci, 2016). On seasonal-to-interannual time scales, CMIP5 models showed a stronger soil-moisture precipitation feedback than estimated by satellite data (Levine et al., 2016). Taylor et al. (2013) found that convection-permitting RCMs simulate well surface-induced mesoscale circulations in day-time convection and the observed negative soil

ACCEPTED VERSION SUBJECT TO FINAL EDITING

moisture feedback, whereas an RCM with parameterised convection, even when run at the same resolution, simulated an unrealistic positive feedback. There is *medium evidence* and *high agreement* that simulations at convection-permitting resolution are required to realistically represent soil-moisture precipitation feedbacks.

Ocean-atmosphere RCMs have successfully been used to understand and simulate phenomena involving strong regional feedbacks like tropical cyclones in the Indian Ocean (Samson et al., 2014), Indian summer monsoon (Samanta et al., 2018), East-Asian summer monsoon (Zou et al., 2016), near-coastline intense precipitation in the Mediterranean (Berthou et al., 2015, 2018b), air-sea fluxes influencing heat and humidity advection over land (Sevault et al., 2014; Lebeaupin Brossier et al., 2015; Akhtar et al., 2018) or snow bands in the Baltic region (Pham et al., 2017). The positive impact of ocean-coupling on the simulation of strongly convective phenomena such as Medicanes, a class of severe cyclones in the Mediterranean, can only be diagnosed when using relatively fine atmospheric resolution of about 10 km (Akhtar et al., 2014; Flaounas et al., 2018; Gaertner et al., 2018). A positive impact of ocean coupling has been quantified in marginal sea regions with reduced large-scale influence (e.g., in the Baltic Sea area during weak phases of the NAO and thus weak influence of Atlantic westerlies (Kjellström et al., 2005; Pham et al., 2018)). There is some evidence that coupled ocean-components also positively impact RCM simulations of inland climates such as precipitation extremes in Central Europe (Ho-Hagemann et al., 2017; Akhtar et al., 2019). There *is high confidence* that coupled ocean-atmosphere RCMs improve the representation of ocean-atmosphere feedbacks and related phenomena.

The influence of ice sheet mass balance on regional climate, explored with global and regional models by (Noël et al., 2018; Fettweis et al., 2020), is discussed in Section 9.4.

10.3.3.6 Performance at simulating regional drivers of climate and climate change

Dust, with its regional character in both emissions and climatic influences, has traditionally been specified in climate simulations with a climatological estimate. In CMIP5 models, the influence of vegetation changes on mineral dust is largely underestimated while the influence of surface wind and precipitation are overestimated, resulting in a low bias of dust load (Pu and Ginoux, 2018). Interactive dust emission modules that simulate the dust optical depth in most of the key emission regions have only been recently introduced (Pu and Ginoux, 2018). However, coarse dust is underestimated in global models (Adebiyi and Kok, 2020). Simulations of future changes in dust are hindered by the uncertainties in future regional wind and precipitation as the climate warms (Evan et al., 2016), in the effect of CO_2 fertilization on source extent (Huang et al., 2017), in the dust feedbacks (Evans et al., 2019), and in the effect of human activities that change land use and disturb the soil, including cropping and livestock grazing, recreation and urbanization, and water diversion for irrigation (Ginoux et al., 2012).

Volcanoes also provide forcings with a marked regional impact (Cross-Chapter Box 4.1). This implies that models are expected to capture these effects (Bethke et al., 2017). Both proxy analyses and simulations have demonstrated reduced Asian monsoon precipitation after tropical and Northern Hemisphere volcanic eruptions due to reduced humidity and divergent circulation (Man and Zhou, 2014; Zhuo et al., 2014; Liu et al., 2016a; Stevenson et al., 2016). Global model experiments (Zanchettin et al., 2013; Ortega et al., 2015; Michel et al., 2018; Sjolte et al., 2018) have suggested that tropical volcanic eruptions (larger than the one from Mount Pinatubo in 1991) may lead to a positive phase of the winter NAO in the following few years (with an uncertainty on the exact years affected), but this influence is not well reproduced in climate models (Driscoll et al., 2012; Toohey et al., 2014; Swingedouw et al., 2017; Ménégoz et al., 2018b). The ability to simulate the effect of volcanic aerosol in global models is evaluated in VolMIP (Zanchettin et al., 2016). Given the relevance of volcanic aerosol, a good knowledge of the initial conditions is important because the response has proven to be sensitive to them (Ménégoz et al., 2018a; Zanchettin et al., 2019). A few decadal prediction systems have illustrated that current systems can predict some aspects of regional climate a few years in advance (Swingedouw et al., 2017; Illing et al., 2018; Ménégoz et al., 2018a; Hermanson et al., 2020). However, a better performance requires information about volcanic location (Haywood et al., 2013; Pausata et al., 2015; Stevenson et al., 2016; Liu et al., 2018a), strength (Emile-Geay et al., 2008; Lim et al., 2016b; Liu et al., 2018b), and seasonality (Stevenson et al., 2017; Sun et al., 2019a, 2019b).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Some recent regional climate changes can only be simulated by climate models if anthropogenic aerosols are correctly included (Sections 10.4.2.1, 10.6.3 and 10.6.4; Chapters 6 and 8). Examples of the importance of correctly representing anthropogenic aerosols are the recent enhanced warming over Europe (Nabat et al., 2014; Dong et al., 2017), the cooling over the East Asian monsoon region, leading to a weakening of the monsoon (Section 8.3.2.4; Song et al., 2014; Wang et al., 2017b), as well as changes in the monsoons of West Africa (Sections 8.3.2.4 and 10.4.2.1) and South Asia (Sections 8.3.2.4 and 10.6.3; Undorf et al., 2018). The relevance of appropriately representing anthropogenic aerosols has been widely studied in regional models (Boé et al., 2020a; Gutiérrez et al., 2020), with an advantage for models with interactive aerosol schemes (Drugé et al., 2019; Nabat et al., 2020). Without a fully coupled chemistry module, radiative forcing can be simulated by including simple models of sulphate chemistry or specifying the optical properties from observations and prescribing the effect of aerosols on the cloud-droplet number (Fiedler et al., 2017, 2019; Stevens et al., 2017). In all cases, the specification of the aerosol load limits the trustworthiness of the simulations at the regional scale when enough detail is not provided (Samset et al., 2019; Shonk et al., 2020; Wang et al., 2021).

The inclusion of irrigation in global and regional models over the South Asian monsoon region (Section 10.6.3) has been found to be important to represent the monsoon circulation and rainfall correctly (Lucas-Picher et al., 2011; Guimberteau et al., 2012; Shukla et al., 2014; Tuinenburg et al., 2014; Cook et al., 2015a; Devanand et al., 2019). Similarly, the inclusion of irrigation over northern India and western Pakistan could be important for the correct simulation of precipitation over the Upper Indus Basin in northern Pakistan (Saeed et al., 2013). Irrigation in the East African Sahel inhibits rainfall over the irrigated region and enhances instead rainfall to the east, coherent with both observations and theoretical understanding of the local circulation anomalies induced by the lower surface air temperatures over the irrigated region (Alter et al., 2015). Although several studies show how modelled irrigation reduces daytime temperature extremes, few compare modelled results with observations. Global model studies have found improvements in simulated surface temperature when including irrigation (Thiery et al., 2017), in particular in areas where the model used has a strong land-atmosphere coupling (Chen and Dirmeyer, 2019). An RCM study over the North China Plain showed that the inclusion of irrigation led to a better representation of the observed night time warming (Chen and Jeong, 2018).

There is *medium confidence* that representing irrigation is important for a realistic simulation of South Asian monsoon precipitation. There is *limited evidence* that including irrigation in climate models improves the simulation of maximum and minimum daily temperatures as well as precipitation for other regions.

Regional land-radiation management, including modifying the albedo through, for instance, no-tillage practices, has been suggested as a measure to decrease regional maximum daily temperatures (see review in Seneviratne et al., 2018), but although modelled results and theoretical understanding are coherent, few studies have verified the results with observations. Hirsch et al. (2018) is an exception, showing that implementing minimal tillage, crop residue management and crop rotation in a global model over regions where it is practiced, improves the simulation of surface heat fluxes.

10.3.3.7 Statistical downscaling, bias adjustment and weather generators

The performance of statistical downscaling models, bias adjustment and weather generators is determined by the chosen model structure (e.g., to represent variability and extremes or spatial dependence) and, if applicable, the predictors selected (Maraun et al., 2019b). The VALUE initiative has assessed a range of such methods in a perfect-predictor experiment where the predictors are taken from reanalysis data (Maraun et al., 2015, 2019b; Gutiérrez et al., 2019). Table 10.2 shows an overview comprising performance results from VALUE and other studies. These results isolate the performance of the statistical method in the present climate. The overall performance in a climate change application also depends on the performance of the driving climate model (Sections 10.3.3.3–10.3.3.6) and the fitness of both the driving model and the statistical method for projecting the climatic aspects of interest (Section 10.3.3.9).

10.3.3.7.1 Performance of perfect prognosis methods

Perfect-prognosis methods can perform well when the synoptic forcing (i.e., the explanatory power of large-scale predictors) is strong (Schoof, 2013). Using this approach, downscaling of precipitation is particularly skilful in the presence of strong orographic forcing. The representation of daily variability and extremes requires analogue methods or stochastic regression models, although the former typically do not extrapolate to unobserved values (Gutiérrez et al., 2019; Hertig et al., 2019). Temporal precipitation variability is well represented by analogue methods and stochastic regression, but analogue methods typically underestimate temporal dependence of temperature (Maraun et al., 2019a). Spatial dependence of both temperature and precipitation is only well represented by analogue methods, for which analogues are defined jointly across locations, and by stochastic regression methods explicitly representing spatial dependence (Widmann et al., 2019). Overall, there is *high confidence* that analogue methods and stochastic regression are able to represent many aspects of daily temperature and variability, but the analogue method is inherently limited in representing climate change (Gutiérrez et al., 2013).

10.3.3.7.2 Performance of bias adjustment methods

This subsection assesses the performance of bias adjustment in a perfect predictor context. In practice, climate model imperfections may cause substantial additional issues in the application of bias adjustment. These are assessed separately in Cross-Chapter Box 10.2.

Bias adjustment methods, if driven by reanalysis predictors, in principle adjust well all the aspects that they intend to address (Maraun and Widmann, 2018b). For temperature, all univariate methods are good for adjusting means, variance, and high quantiles (Gutiérrez et al., 2019; Hertig et al., 2019). For precipitation, means, intensities, wet-day frequencies, and wet-dry and dry-wet transitions are well adjusted (Gutiérrez et al., 2019; Maraun et al., 2019a). The representation of high quantiles depends on the chosen method, although flexible quantile mapping performs best (Hertig et al., 2019). Empirical (non-parametric) methods perform better than parametric methods over the observed range, but it is unclear how this translates into extrapolation to unobserved values (Hertig et al., 2018; Stocker et al., 2015). Many quantile mapping methods overestimate interannual variability (Maraun et al., 2019a). Temporal and spatial dependence are usually not adjusted and thus inherited from the driving model (Maraun et al., 2019a; Widmann et al., 2019). Spatial fields are thus typically too smooth in space, even after bias adjustment (Widmann et al., 2019).

Several studies show improved simulations of present day impacts, when the impact model is fed with bias-adjusted climate model output, including the assessment of river discharge (Rojas et al., 2011; Muerth et al., 2013; Montroull et al., 2018), forest fires (Migliavacca et al., 2013), crop production (Ruiz-Ramos et al., 2016), and regional ocean modelling (Macias et al., 2018).

There is *high confidence* that bias adjustment can improve the marginal distribution of simulated climate variables, if applied to a climate model that adequately represents the processes relevant for a given application (Cross-Chapter Box 10.2).

10.3.3.7.3 Performance of weather generators

Weather generators represent well most aspects that are explicitly calibrated. This typically includes mean, variance, high quantiles (for precipitation, if explicitly modelled), and short-term temporal variability for both temperature and precipitation, whereas interannual variability is strongly underestimated (Frost et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2011; Hu et al., 2013a; Keller et al., 2015; Dubrovsky et al., 2019; Gutiérrez et al., 2019; Hertig et al., 2019; Maraun et al., 2019a; Widmann et al., 2019). There is growing evidence that some spatial weather generators fairly realistically capture the spatial dependence of temperature and precipitation (Frost et al., 2011; Hu et al., 2013a; Keller et al., 2015; Evin et al., 2018; Dubrovsky et al., 2019). There is *high confidence* that weather generators can realistically simulate a wide range of local weather characteristics at single locations, but there is *limited evidence* and *low agreement* of the ability of weather generators to realistically simulate the spatial dependence of atmospheric variables across multiple sites.

10.3.3.8 Performance at simulating historical regional climate changes

This section assesses how well climate models perform at realistically simulating historical regional climatic trends. Current global model ensembles reproduce global to continental-scale surface temperature trends at multi-decadal to centennial time scales (CMIP5, CMIP6), but underestimate precipitation trends (CMIP5) (Sections 3.3.1 and 3.3.2). For regional trends, AR5 concluded that the CMIP5 ensemble cannot be taken as a reliable representation of reality and that the true uncertainty can be larger than the simulated model spread (Kirtman et al., 2014). Case studies of regional trend simulations by global models can be found in Sections 10.4.1 and 10.6, and region-by-region assessments in the Atlas. A key limitation for assessing the representation of regional observed trends by single transient simulations of global models (or downscaled versions thereof) is the strong amplitude of internal variability compared to the forced signal at the regional scale (Section 10.3.4.3). Even on multidecadal time scales, an agreement between observed and individual simulated trends would be expected to occur only by chance (Laprise, 2014).

In the context of downscaling, the ability of downscaling methods to reproduce observed trends when driven with boundary conditions or predictors taken from reanalysis data (which reproduce the observed internal variability on long time scales) can be assessed. For temperature in the continental USA, reanalysis-driven RCMs skilfully simulated recent spring and winter trends, but did not reproduce summer and autumn trends, (Bukovsky, 2012). Over Central America, observed warming trends were reproduced (Cavazos et al., 2019). In contrast, a reanalysis-driven coupled atmosphere-ocean RCM covering the Mediterranean could not reproduce the observed SST trend (Sevault et al., 2014).

Similar studies have been carried out for statistical downscaling and bias adjustment using predictors from reanalyses (or in case of bias adjustment, dynamically downscaled reanalyses). For a range of different perfect prognosis methods, Huth et al. (2015) found that simulated temperature trends were too strong for winter and too weak for summer. The performance was similar for the different methods, indicating the importance of choosing sensible predictors. Similarly, Maraun et al. (2017) found that the performance of perfect prognosis methods depends mostly on the predictor and domain choice (for instance, temperature trends were only captured by those methods including surface temperature as predictor). Bias adjustment methods reproduced the trends of the driving reanalysis, apart from quantile mapping methods, which deteriorated these trends.

RCM experiments are often set up such that changes in forcing agents are included only via the boundary conditions, but not explicitly included inside the domain. Jerez et al. (2018) demonstrated that not including time-varying GHG concentrations within the RCM domain may misrepresent temperature trends by 1–2ºC per century. Including the past trend in anthropogenic sulphate aerosols in reanalysis-driven RCM simulations substantially improved the representation of recent brightening and warming trends in Europe (Nabat et al., 2014; Section 10.3.3.6, 10.6.4, Atlas 8.4). Similarly, Bukovsky (2012) argued that RCMs may not capture observed summer temperature trends in the USA because changes in land cover are not taken into account. Barlage et al. (2015) have revealed that including the behaviour of groundwater in land schemes increases the performance of an RCM model to represent climate variability in the central USA. Hamdi et al. (2014) found that an RCM that did not incorporate the historical urbanization in the land-use, land-cover scheme is not able to reproduce the warming trend observed in urban stations, with a larger bias for the minimum temperature trend.

Overall, there is *high confidence* that including all relevant forcings is a prerequisite for reproducing

ACCEPTED VERSION SUBJECT TO FINAL EDITING

historical trends.

10.3.3.9 Fitness of climate models for projecting regional climate

AR5 stated that confidence in climate model projections is based on the physical understanding of the climate system and its representation in climate models. A climate model's credibility for future projections may be increased if the model is able to simulate past variations in climate (Flato et al., 2014; Sections 10.3.3.8, 10.4.1 and 10.6). In particular, the credibility of downscaled information depends on the quality of both the downscaling method and of the global model providing the large-scale boundary conditions (Flato et al., 2014). Credibility is closely linked to the concept of adequacy or fitness for purpose (Parker, 2009; Section 1.5.4.1). From a regional perspective, one may ask about the fitness of a climate model for simulating future changes of specific aspects of a specific regional climate. The required level of model fitness may depend on the user context (Section 10.5). A key challenge is to link performance at representing present and past climate (Sections 10.3.3.3 to 10.3.3.8) to the confidence in future projections (Section 1.3.5; Baumberger et al., 2017) and it is addressed in this subsection.

A general idea of model fitness for a given application may be obtained by checking whether relevant large- (Section 10.3.3.4) and regional-scale (Sections 10.3.3.5 and 10.3.3.6) processes are explicitly resolved (Figure 10.3). The basis for confidence in climate projection is a solid process understanding (Flato et al., 2014; Baumberger et al., 2017). Thus, the key to assessing the fitness for purpose of a model is the evaluation of how relevant processes controlling regional climate are represented (Collins et al., 2018). A process-based evaluation may be more appropriate than an evaluation of the variables of interest (e.g., temperature, precipitation), because biases in the latter may in principle be reduced if the underlying processes are realistically simulated (Cross-Chapter Box 10.2), while individual variables may appear as well represented because of compensating errors (Flato et al., 2014; Baumberger et al., 2017). Combining a process-based evaluation with a mechanistic explanation of projected changes further increases confidence in projections (Bukovsky et al., 2017). Fitness-for-purpose can also be assessed by comparing the simulated response of a model with simulations of higher resolution models that better represent relevant processes (Baumberger et al., 2017). For instance, Giorgi et al. (2016) have corroborated their findings on precipitation changes comparing standard RCM simulations with convection-permitting simulations.

The evaluation of model performance at historical variability and long-term changes provides further relevant information (Flato et al., 2014). Trend evaluation may provide very useful insight, but has limitations in particular at the regional scale, mainly due to multi-decadal internal climate variability (Section 10.3.3.8), observational uncertainty (in both driving reanalysis and local trends; Section 10.2), and the fact that often not all regional forcings are known, and that past trends may be driven by forcings other than those driving future trends (Sections 10.4.1 and 10.6.3).

Increasing resolution (Haarsma et al., 2016) or performing downscaling may be particularly important when it modifies the climate change signal of a lower resolution model in a physically plausible way (Hall, 2014). Improvements may result from a better representation of regional processes, upscale effects, as well as the possibility of a region-specific model tuning (Sørland et al., 2018). For instance, Gula and Peltier (2012) showed that a higher resolution allows for a more realistic simulation of lake-induced precipitation, resulting in a more credible projection of changes in the snow belts of the North American Great Lakes. Similarly, Giorgi et al. (2016) demonstrated that an ensemble of RCMs better represents high-elevation surface heating and in turn increased convective instability. As a result, the summertime convective precipitation response was opposite to that simulated by the driving global models (Figure 10.9). Similarly, Walton et al. (2015) showed that a kilometre-scale RCM enables a more realistic representation of the snow-albedo feedback in mountainous terrain compared to standard resolution global models, leading to a more plausible simulation of elevation-dependent warming. Bukovsky et al. (2017) argue that strong seasonal changes in warm-season precipitation in the Southern Great Plains of the US, projected by RCMs, are more credible than the weaker global model changes because precipitation is better simulated in the RCMs.

[START FIGURE 10.9 HERE]

Figure 10.9: Projected changes in summer (June to August) precipitation (in percent with respect to the mean precipitation) over the Alps between the periods 2070–2099 and 1975–2004. (a) Mean of four GCMs regridded to a common 1.32°x1.32° grid resolution; (b) mean of six RCMs driven with these GCMs. The grey isolines show elevation at 200 m intervals of the underlying model data. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11). Adapted from Giorgi et al. (2016).

[END FIGURE 10.9 HERE]

Including additional components, feedbacks and drivers can substantially modify the simulated future climate. For example, Kjellström et al. (2005) and Somot et al. (2008) have shown that a regional ESM can significantly modify the SST response to climate change of its driving global model with implications for the climate change signal over both the sea and land. In particular, coupled ocean-atmosphere RCMs may increase the credibility of projections in regions of strong air-sea coupling such as the East Asia-western North Pacific domain (Zou and Zhou, 2016b, 2017). Recent studies demonstrate the importance of including regional patterns of evolving aerosols in RCMs for simulating regional climate change (Boé et al., 2020a; Gutiérrez et al., 2020). RCMs not including the plant physiological response to increasing CO_2 concentrations have been shown to substantially underestimate projected increases in extreme temperatures across Europe compared to GCMs that explicitly model this effect (Schwingshackl et al., 2019).

A difference between the climate changes simulated by two models does not automatically imply the more complex or higher resolution model is superior (e.g., Dosio et al., 2019). Studies comparing convection-permitting RCM simulations to simulations of climate models with parameterized convection find, depending on the considered models, regions and seasons, either similar or qualitatively different projected changes in short duration extreme precipitation (Chan et al., 2014b, 2014a, 2020; Ban et al., 2015; Tabari et al., 2016; Fosser et al., 2017; Kendon et al., 2017, 2019; Vanden Broucke et al., 2018). Process studies provide evidence that convection-permitting simulations better represent crucial local and mesoscale features of convective storms and thus simulate more plausible changes (Meredith et al., 2015a; Prein et al., 2017; Fitzpatrick et al., 2020), but further research is required to confirm and reconcile the different findings.

Studies assessing the fitness of statistical approaches for regional climate projections are still very limited in number. For statistical downscaling, a key issue is to include predictors that control long-term changes in regional climate. Models differing only in the choice of predictors may perform similarly in the present climate, but may project opposite precipitation changes (Fu et al., 2018; Manzanas et al., 2020). In addition to trend-evaluation studies (Section 10.3.3.8), perfect-model experiments (Section 10.3.2.5) have been used to assess whether a given model structure with a chosen set of predictors is capable of reproducing the simulated future climates (Gutiérrez et al., 2013; Räty et al., 2014; Dayon et al., 2015; Dixon et al., 2016; San-Martín et al., 2017). Importantly, it is found that standard analogue methods inherently underestimate future warming trends because of missing analogues for a warmer climate (Gutiérrez et al., 2013).
Bias adjustment assumes that model biases are time invariant (or more precisely, independent of the climate state), such that the adjustment made to present climate simulations is still applicable to future climate simulations. Many findings challenge the validity of this assumption, as already assessed in AR5 (Flato et al., 2014). Further research has addressed this issue by means of perfect model experiments (Section 10.3.2.5) and process understanding. Perfect-model studies with GCMs found that circulation, energy, and water-cycle biases are roughly state-independent (Krinner and Flanner, 2018), whereas temperature biases depend linearly on temperature (Kerkhoff et al., 2014). Others show that regional temperature biases may depend on soil moisture and albedo, and may thus be state-dependent (Maraun, 2012; Bellprat et al., 2013; Maraun et al., 2017; see Cross-Chapter Box 10.2 for further limitations of bias adjustment). The fitness of weather generators for future projections depends on whether they account for all relevant changes in their parameters, either by predictors or change factors (Maraun and Widmann, 2018b).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

In any case, the fitness of regional climate projections based on dynamical downscaling or statistical approaches depends on the fitness of the driving models in projecting boundary conditions, predictors and change factors (Hall, 2014; Maraun and Widmann, 2018b).

Overall, there is *high confidence* that an assessment of model fitness for projections applying process-based evaluation, process-based plausibility checks of projections and a comparison of different model types, increases the confidence in climate projections. There is *high confidence* that increasing model resolution, dynamical downscaling, statistical downscaling with well simulated predictors controlling regional climate change, and adding relevant model components can increase the fitness for projecting some aspects of regional climate when accompanied by a process-understanding analysis.

10.3.3.10 Synthesis of model performance at simulating regional climate and climate change

Global models reproduce many of the features of observed climate and its variability at regional scales. However, global models can show a variety of biases in, for instance, precipitation and temperature at scales ranging from continental (Prasanna, 2016) to sub-continental scales (Lovino et al., 2018), both in the mean and in higher order moments of the climatological distribution of the variable (Ren et al., 2019; Xin et al., 2020; Figure 10.6). Regional biases could occur even if all the relevant large-scale processes are correctly represented, but not their interaction with regional features such as orography or land-sea contrasts (Section 10.3.3.4). These biases have been considered an important limiting factor in model usability, especially at the regional scale (Palmer, 2016). In spite of this, global model simulations have been extensively used to create regional estimates of climate change (Chapters 11, 12 and Atlas), taking into account the result of a performance assessment (e.g., Jiang et al., 2020; Sections 10.3.3.3 to 10.3.3.8, Chapters 11 and Atlas). However, their application is limited in part by the effective resolution of these models (Klaver et al., 2020).

Global model performance at the regional scale is assessed in terms of the time or spatial averages of key variables (Brunner et al., 2019; Chapter Atlas), the ability to reproduce their seasonal cycle (Hasson et al., 2013) or a set of extreme climate indicators (Luo et al., 2020; Chapter 11) and the representation of regional processes and phenomena, feedbacks, drivers and forcing impacts (Sections 10.3.3.4–10.3.3.6). In many cases, the performance estimates have been used to select models for either an application or a more in-depth study (Lovino et al., 2018), to select the models that provide boundary conditions to perform RCM simulations (McSweeney et al., 2015) or to weight the results of the GCM simulations (Sanderson et al., 2015; Brunner et al., 2020). While some large-scale metrics are improved between the CMIP5 and CMIP6 experiments (e.g., Cannon, 2020; Chapter 3), there is not yet concluding evidence of a systematic improvement for surface variables at the regional scale.

The special class of high-resolution global models (Haarsma et al., 2016; Prodhomme et al., 2016; Sections 1.5.3.1 and 10.3.3.1, Chapter 3) is expected to improve some of the regional processes that are not appropriately represented in standard global models (Roberts et al., 2018). There is general consensus that increasing global model resolution improves some long-standing biases (Demory et al., 2014, 2020; Schiemann et al., 2014; Dawson and Palmer, 2015; van Haren et al., 2015; Feng et al., 2017; Fabiano et al., 2020; Chapter 3 and 10.3.3.3; Figures 10.6 and 10.7), although the resolution increase is not a guarantee of overall improvement (Fabiano et al., 2020; Hertwig et al., 2021; Section 8.5.1). For instance, increasing resolution in global models has been shown to improve Asian monsoon rainfall anchored to orography and the monsoon circulation (Johnson et al., 2016), but fails to solve the major dry bias. It is also difficult to disentangle the role of resolution increase and model tuning on the performance of the GCM (Anand et al., 2018). Some efforts have been undertaken to complement the performance improvements of resolution by using stochastic parameterisations (Palmer, 2019), which explicitly acknowledge the multi-scale nature of the climate system, in standard resolution global models with some success (Dawson and Palmer, 2015; MacLeod et al., 2016; Zanna et al., 2017, 2019). The expectation is to achieve a similar performance to the increase in resolution at a reduced computational cost.

Despite their known errors that affect model performance, there is *high confidence* that global models provide useful information for the production of regional climate information. There is *robust evidence* and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

high agreement that the increase of global model resolution helps in reducing the biases limiting performance at the regional scale, although resolution per se does not automatically solve all performance limitations shown by global models. There is *robust evidence* that stochastic parameterisations can help to improve some aspects of the global model performance that are relevant to regional climate information.

Global models tend to have difficulties in simulating climate over regions where unresolved local scale processes, feedbacks and nonlinear scale interactions result in a degradation of the model performance compared to models with higher resolution. In this case, RCMs and variable resolution global models can resolve part of these processes in the regions of interest at an acceptable computational cost (Rummukainen, 2016; Giorgi, 2019; Gutowski et al., 2020).

The assessment of RCM performance needs to focus not only on mean climatology (Atlas), but also trends (Section 10.3.3.8) and extremes (Chapter 11), and the RCM's ability at correctly reproducing relevant processes, forcings and feedbacks (including e.g., aerosols, plant responses to increasing CO_2, etc., Schwingshackl et al., 2019; Boé et al., 2020; Sections 11.2. and 10.3.3.3 to 10.3.3.8) to be fit for future projections (Section 10.3.3.9).

When RCMs are driven by global models, part of the uncertainty in the RCM simulation is introduced by the global model biases (Kjellström et al., 2018; Sørland et al., 2018; Christensen and Kjellström, 2020). As RCMs are typically not able to mitigate global model biases in large-scale dynamical processes, if such biases are substantial, and if the corresponding large-scale processes are important drivers of regional climate, downscaling is questionable (Section 10.3.3.3). However, when global models have weak circulation biases and regional climate change is controlled mainly by regional-scale processes and feedbacks, dynamical downscaling has the potential to add substantial value to global model simulations (Hall, 2014; Rummukainen, 2016; Giorgi, 2019; Schwingshackl et al., 2019; Boé et al., 2020; Lloyd et al., 2020; Section 10.3.3.4 and Chapter Atlas).

There is *very high confidence* (*robust evidence* and *high agreement*) that RCMs add value to global simulations in representing many regional weather and climate phenomena, especially over regions of complex orography or with heterogeneous surface characteristics and for local-scale phenomena. Realistically representing local-scale phenomena such as land-sea breezes requires simulations at a resolution of the order of 10 km (*high confidence*). Simulations at kilometre-scale resolution add value in particular to the representation of convection, sub-daily summer precipitation extremes (*high confidence*) and soil moisture-precipitation feedbacks (*medium confidence*). Resolving regional processes may be required to correctly represent the sign of regional climate change (*medium confidence*). However, the performance of RCMs and their fitness for future projections depend on their representation of relevant processes, forcings and drivers in the specific context (Sections 10.3.3.4–10.3.3.8).

Statistical downscaling, bias adjustment and weather generators outperform uncorrected output of global and regional models for a range of statistical aspects at single locations due to their calibration, but RCMs are superior when spatial fields are relevant (Mehrotra et al., 2014; Vaittinada Ayar et al., 2016; Maraun et al., 2019b). Similarly, there is some evidence that bias adjustment is comparable in performance when applied to global models and dynamically downscaled global models only for single locations, but dynamical downscaling prior to bias adjustment clearly adds value once spatial dependence is relevant (Maraun et al., 2019b). These results may explain why dynamical downscaling does not add value to global model simulations for (single-site) agricultural modelling, when both global and regional model are bias adjusted (Glotter et al., 2014), but dynamical downscaling adds value compared to bias adjusted global model output for spatially distributed hydrological models (Qiao et al., 2014).

Overall, statistical downscaling methods with carefully chosen predictors and an appropriate model structure for a given application realistically represent many statistical aspects of present-day daily temperature and precipitation (*high confidence*, Section 10.3.3.7). Bias adjustment has proven beneficial as an interface between climate model projections and impact modelling in many different contexts (*high confidence*, Section 10.3.3.7). Weather generators realistically simulate many statistical aspects of present-day daily temperature and precipitation (*high confidence*, Section 10.3.3.7). The performance of these approaches and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

their fitness for future projections also depends on predictors and change factors taken from the driving dynamical models (*high confidence*, Section 10.3.3.9).

10.3.4 Managing Uncertainties in Regional Climate Projections

Regional climate projections are affected by three main sources of uncertainty (Sections 10.2.2, 1.4.3 and 4.2.5): unknown future external forcings, imperfect knowledge and implementation of the response of the climate system to external forcings, and internal variability (Lehner et al., 2020). In a regional downscaling context, uncertainties arise in every step of the modelling chain. Here the propagation of uncertainties (Section 10.3.4.1), the management of uncertainties (Section 10.3.4.2), the role of the internal variability for regional projections (Section 10.3.4.3), and the design and use of ensembles to account for uncertainties (Section 10.3.4.4) will be assessed. Observational uncertainty, in particular for the calibration of statistical downscaling methods (Section 10.2.3.1), also contributes to projection uncertainty.

10.3.4.1 Propagation of uncertainties

Modelling chains for generating regional climate information range from the definition of forcing scenarios to the global modelling, and potentially to dynamical or statistical downscaling and bias adjustment (Section 10.3.1). The propagation and potential accumulation of uncertainties along the chain has been termed the cascade of uncertainty (Wilby and Dessai, 2010). Even within one model, like a global model, uncertainty propagates across scales. From a process point of view, these uncertainties are related to forcings and global climate sensitivity, and errors in the representation of the large-scale circulation (McNeall et al., 2016; Section 10.3.3.3) and regional processes (Section 10.3.3.4), feedbacks (Section 10.3.3.5) and drivers (Section 10.3.3.6). From a modelling point of view, these uncertainties are related to the choice of dynamical and statistical models (Section 10.3.1) and experimental design (Section 10.3.2). The overall uncertainty can be statistically decomposed into the individual sources (Evin et al., 2019; Christensen and Kjellström, 2020), although there might be nonlinear dependencies between them.

Uncertainty propagation often increases the spread in regional climate projections when comparing global model and downscaled results, which has been used as an argument against top-down approaches to climate information (Prudhomme et al., 2010). Increased spread in the modelling chain may also arise from a more comprehensive representation of previously unknown or underrepresented uncertainties (Maraun and Widmann, 2018b). The increased spread in this case goes together with a better representation of processes and thus an increased model fitness for purpose (Section 10.3.3.9).

10.3.4.2 Representing and reducing uncertainties

Climate response uncertainties (Chapter 1) can be represented by multi-model ensembles, although the sampled uncertainty typically underestimates the full range of uncertainty (Collins et al., 2013b; Shepherd et al., 2018; Almazroui et al., 2021). Traditionally, climate response uncertainty has been characterized by the ensemble spread around the multi-model mean change. The change has then further been qualified in terms of the agreement across models and compared to estimates of internal climate variability (Collins et al., 2013b). Since AR5, several limitations of this approach have been identified (Madsen et al., 2017) such as the failure to address physically plausible, but low probability high-impact scenarios (Chapters 1, 4, 8 and 9; Sutton, 2018) or that qualitatively different or even opposite changes may be equally plausible at the regional scale (Shepherd, 2014). In a multi-model mean these different responses would be lumped together, strongly dampened, and qualified as non-robust, whereas in fact high impacts might occur. Further, the multi-model mean itself is often implausible because it is a statistical construct (Zappa and Shepherd, 2017). Overall, there is *high confidence* that some regional future climate changes are not well characterised by multi-model mean and spread.

Since AR5, physical climate storyline approaches (see also Chapter 1, Box 10.2, Section 10.5.3, and Atlas

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2.5.2) have been developed to better characterise and communicate uncertainties in regional climate projections (Shepherd, 2019). A special class of such storylines attempts to attribute regional uncertainties to uncertainties in remote drivers. For instance, the Dutch Meteorological Service has presented climate projections for the Netherlands for different plausible changes of the mid-latitude atmospheric circulation and different levels of European warming (van den Hurk et al., 2014). Manzini et al. (2014) have quantified the impact of uncertainties in tropical upper troposphere warming, polar amplification, and stratospheric wind change on Northern Hemisphere winter climate change. Based on these results, Zappa and Shepherd (2017) separated the multi-model ensemble into physically consistent sub-groups or storylines of qualitatively different projections in relevant remote drivers of the atmospheric circulation. In a similar vein, (Ose et al., 2020) trace uncertainties in projections of the East Asian summer monsoon and Mindlin et al. (2020) conditioned the response of Southern Hemisphere mid-latitude circulation and precipitation to greenhouse gas forcing on large-scale climate indicators (Section 8.4.2.9.2).

These physical climate storylines help to physically explain contradicting regional projections and thus make the conveyed information a better representation of the true uncertainty (Hewitson et al., 2014a). Additionally, the attribution of regional uncertainties to drivers may in principle help reduce uncertainty in the case where some storylines can be ruled out because the projected changes in the driving processes appear to be physically implausible (Zappa and Shepherd, 2017). There is thus *high confidence* that storylines attributing uncertainties in regional projections to uncertainties in changes of remote drivers aid the interpretation of uncertainties in climate projections.

Another approach that has continued to develop for characterising and reducing projection uncertainties is the use of emergent constraints (Hall et al., 2019; Chapters 1, 4, 5, 7). The idea is to link the spread in climate model projections via regression to the spread in present climate model biases for relevant driving processes. Models with lower biases are assigned higher weight in the projections, which in turn reduces the spread of the projections in a physical way and may additionally reduce projection uncertainty. For instance, Simpson et al. (2016) have reduced the spread in projections of North American winter hydroclimate by linking this spread to model biases in the representation of relevant stationary wave patterns. Other examples of using emergent constraints in a regional context are Brown et al. (2016), Li et al. (2017), Giannini and Kaplan (2019), Ose (2019) and Zhou et al.(2019).

10.3.4.3 Role of internal variability

A regional climate projection based on a single simulation from a single global model or driving a single RCM alone will inevitably be affected by not taking into account the internal variability (Figure 10.10). This is mainly due to the dominant influence of the chaotic atmospheric circulation on regional climate variability, in particular at mid-to-high latitudes. Internal variability is an irreducible source of uncertainty for mid-to-long-term projections with an amplitude that typically decreases with increasing spatial scale and lead time (Section 1.4.3; Section 4.2.1). However, regional-scale studies show that both large- and local-scale internal variability together can still represent a substantial fraction of the total uncertainty related to hydrological cycle variables, even at the end of the 21st century (Lafaysse et al., 2014; Vidal et al., 2016; Aalbers et al., 2018; Gu et al., 2018).

Analysis of multi-model archives such as CMIP or CORDEX simulation results cannot easily disentangle model uncertainty and uncertainty related to internal variability. Since AR5, the development of single-model (GCM and/or RCM) initial-condition large ensembles (SMILEs) has emerged as a promising way to robustly assess the regional-scale forced response to external forcings and the respective contribution of internal variability and model uncertainty to future regional climate changes (Deser et al., 2014, 2020; Kay et al., 2015; Sigmond and Fyfe, 2016; Aalbers et al., 2018; Bengtsson and Hodges, 2018; von Trentini et al., 2019b; Dai and Bloecker, 2019; Leduc et al., 2019; Maher et al., 2019; Lehner et al., 2020; Section 4.2.5). The recent development of a multi-model archive of SMILE simulations facilitates the quantification and comparison of the influence of internal variability on global model-based regional climate projections between different models (Deser et al., 2020; Lehner et al., 2020). Another related development is the more frequent use of observation-based statistical models to assess the influence of internal variability on regional-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

scale global and regional model projections (Thompson et al., 2015; Salazar et al., 2016). However, these methods often implicitly assume that regional-scale internal variability does not change under anthropogenic forcing, which is a strong assumption that does not seem to hold at regional and local scales (LaJoie and DelSole, 2016; Pendergrass et al., 2017; Cai et al., 2018b; Dai and Bloecker, 2019; Mankin et al., 2020; Milinski et al., 2020).

[START FIGURE 10.10 HERE]

Figure 10.10: Observed and projected changes in austral summer (December to February) mean precipitation in GPCC, CRU TS and 100 members of the MPI-ESM. (a) 55-year trends (2015–2070) from the ensemble members with the lowest (left) and highest (right) trend (% per decade, baseline 1995–2014). (b) Time series (%, baseline 1995–2014) for different spatial scales (from top to bottom: global averages; S.E. South America; grid boxes close to São Paulo and Buenos Aires) with a five-point weighted running mean applied (a variant on the binomial filter with weights [1-3-4-3-1]). The brown (green) lines correspond to the ensemble member with weakest (strongest) 55-year trend and the grey lines to all remaining ensemble members. Box-and-whisker plots show the distribution of 55-year linear trends across all ensemble members, and follow the methodology used in Figure 10.6. Trends are estimated using ordinary least squares. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.10 HERE]

The appropriate ensemble size for a robust use of SMILEs depends on the model and physical variable being investigated, the spatial and time aggregation being performed, the magnitude of the acceptable error and the type of questions one seeks to answer (Deser et al., 2012, 2017b; Kang et al., 2013; Wettstein and Deser, 2014; Dai and Bloecker, 2019; Maher et al., 2019). It is noteworthy that the recent development of ensembles with a very large ensemble size (greater than 100) have led to new insights and methodologies to robustly assess the required ensemble size for questions such as the estimation of the forced response to external forcing or a forced change in modes of internal variability, such as ENSO, and its associated teleconnections (Herein et al., 2017; Maher et al., 2018; Haszpra et al., 2020; Milinski et al., 2020).

The use of SMILEs assumes that they have a realistic representation of internal variability and its evolution under anthropogenic climate change (Eade et al., 2014; McKinnon et al., 2017; McKinnon and Deser, 2018; Chen and Brissette, 2019). Assessing the realism of simulated internal variability for past and current climates remains an active research field with a number of issues such as the shortness and uncertainties of the observed record, in particular in data-scarce regions (Section 10.2.2.3), the signal-to-noise paradox (Scaife and Smith, 2018; Section 4.4.3.1), uncertainty in past observed external forcing estimates (Chapters 2, 6 and 7) and the limitations of assumptions underlying the statistical methods used to derive observational large ensembles (McKinnon et al., 2017; McKinnon and Deser, 2018; Castruccio et al., 2019). Calibration methods inspired by weather and seasonal forecasts can be used to improve the reliability of regional-scale climate projections from large ensembles (Brunner et al., 2019; O'Reilly et al., 2020). Interestingly, reliability is improved when the calibration is performed separately for the dynamical and residual components of the ensemble resulting from dynamical adjustment (O'Reilly et al., 2020; Section 10.4.1).

Importantly, accurately partitioning uncertainty in regional climate projections can provide an incentive for immediate action, accepting a large range of possible outcomes due to internal variability, while confounding model uncertainty with internal variability may be understood as a lack of knowledge and lead to delayed action in adaptation decision-making (Maraun, 2013; Mankin et al., 2020; Section 10.5.3).

There is *high confidence* that the availability of SMILEs allows a robust assessment of the relative contributions of model uncertainty and internal variability in regional-scale projection uncertainty. There is *high confidence* that the use of SMILEs with appropriate ensemble size leads to an improved estimate of regional-scale forced response to an external forcing as well as of the full spectrum of possible changes associated with internal variability. There is *high confidence* that these improved estimates are beneficial for

ACCEPTED VERSION SUBJECT TO FINAL EDITING

characterizing the full distribution of outcomes that is a key ingredient of climate information for robust decision-making and risk-analysis frameworks.

10.3.4.4 Designing and using ensembles for regional climate change assessments to take uncertainty into account

Ensembles of climate simulations play an important role in quantifying uncertainties in the simulation output (Sections 10.3.4.2 and 10.3.4.3). In addition to providing information on internal variability, ensembles of simulations can estimate scenario uncertainty and model (structural) uncertainty. Chapter 4, especially Box 4.1, discusses issues involved with evaluating ensembles of GCM simulations and their uncertainties. In a downscaling context, further considerations are necessary, such as the selection of GCM-RCM combinations when performing dynamical downscaling. This is a relevant issue when resources are limited. The structural uncertainty of both the GCM and the downscaling method can be important (e.g., Dosio, 2017; Mearns et al., 2012), as well as further potential uncertainty created by inconsistencies between the GCM and the downscaling method (e.g., Dosio et al., 2019), which could include, for example, differences in topography or the way to model precipitation processes (Mearns et al., 2013).

An important consideration is which set of GCMs should be used for GCM-RCM combinations. If adequate resources exist, then large numbers of GCM-RCM combinations are possible (Déqué et al., 2012; Vautard et al., 2020; Coppola et al., 2021). However, coordinated downscaling programmes can be limited by the human and computational resources available, for producing ensembles of downscaled output, which limits the number of feasible GCM-RCM combinations. With this limitation in mind, a small set of GCMs may be chosen that span the range of equilibrium climate sensitivity in available GCMs (e.g., Inatsu et al., 2015; Mearns et al., 2012, 2013), though this range may be inconsistent with the likely range (Chapter 4), or some other relevant measure of sensitivity, such as the projected range of tropical SSTs (Suzuki-Parker et al., 2018). A further choice is to emphasize models that do not have the same origins or that do not use similar parameterizations and thus might be viewed as independent, a criterion that could be applied to both GCMs (Chapter 4) and RCMs (Evans et al., 2014). GCMs and RCMs could also be discarded that unrealistically represent processes controlling the regional climate of interest (McSweeney et al., 2015; Maraun et al., 2017; Bukovsky et al., 2019; Eyring et al., 2019). Box 4.1 offers a more detailed discussion of the issues surrounding these approaches. Finally, GCMs may be selected to represent different physically self-consistent changes in regional climate (Zappa and Shepherd, 2017). Statistical methods can provide estimates of outcomes from missing GCM-RCM combinations in a large matrix (Déqué et al., 2012; Heinrich et al., 2014; Evin et al., 2019).

However, even using a relatively small set of GCMs can still involve substantial computation that strains available resources, both for performing the simulations and for using all simulations in the ensemble for further impacts assessment. The NARCCAP programme (Mearns et al., 2012) used only a subset of its possible GCM-RCM combinations that balanced comprehensiveness of sampling the matrix with economy of computation demand, while still allowing discrimination, via ANOVA methods, of GCM and RCM influences on regional climate change (Mearns et al., 2013). An advantage of the sparse, but balanced matrix for those using the downscaling output for further studies, is that they have a smaller, yet comprehensive set of GCM-RCM combinations to work with. Alternatively, data-clustering methods can clump together downscaling simulations featuring similar climate-change characteristics, so that only one representative simulation from each cluster may be needed for further impacts analysis, again systematically reducing the necessary number of simulations to work with (Mendlik and Gobiet, 2016; Wilcke and Bärring, 2016).

Independently of the resources, participation of multiple models in a simulation programme such as CORDEX for RCMs or CMIP for GCMs creates ensembles of opportunity, which are ensembles populated by models that participants chose to use without there necessarily being an overarching guiding principle for an optimum choice. As discussed in Chapter 4, these ensembles are likely suboptimal for assessing sources of uncertainty. An important contributor to the suboptimal character of such an ensemble is that the models are not independent. Some may also have larger biases than others. Yet often, the output from models in these ensembles has received equal weight when viewed collectively, as was the case in much of the AR5

ACCEPTED VERSION SUBJECT TO FINAL EDITING

assessment (e.g., Collins et al., 2013; Flato et al., 2014; Kirtman et al., 2014; Knutti et al., 2013). A number of emerging methodologies aim at optimizing the ensembles available by weighting the simulation results according to a number of criteria relevant at the regional scale that aim at obtaining more realistic estimates of the uncertainty (Sanderson et al., 2015; Brunner et al., 2020)

There is *high confidence* that ensembles for regional climate projections should be selected such that models unrealistically simulating processes relevant for a given application are discarded, but at the same time, the chosen ensemble spans an appropriate range of projection uncertainties.

Cross-Chapter Box 10.2: Relevance and limitations of bias adjustment

Coordinators: Alessandro Dosio (Italy), Douglas Maraun (Austria/Germany)
Contributors: Ana Casanueva (Spain), José M. Gutiérrez (Spain), Stefan Lange (Germany), Jana Sillmann (Norway/Germany)

Bias adjustment is an approach to post-process climate model output and has become widely used in climate hazard and impact studies (Gangopadhyay et al., 2011; Hagemann et al., 2013; Warszawski et al., 2014) and national assessment reports (Cayan et al., 2013; Georgakakos et al., 2014). Despite its wide use, bias adjustment was not assessed in AR5 (Flato et al., 2014). Several problems have been identified that may arise from an uncritical use of bias adjustment, and that may result in misleading impact assessments. The rationale of this Cross-Chapter Box is to provide an overview of the use of bias adjustment in this report, and to assess key limitations of the approach.

Bias-adjusted climate model output is used extensively throughout this report. Several results from Chapter 8, and many of the climatic impact-drivers in Chapter 12 (Section 12.2) are based on bias adjustment. The Atlas presents many results both as raw and bias-adjusted data (Atlas.1.4.5). The application of bias adjustment in the WGI1 report was informed by the assessment in Chapter 10 and this Cross-Chapter Box. Finally, bias adjustment is crucial for many studies assessed in the WG II report. An overview of bias adjustment can be found in Section 10.3.1.3, a general performance assessment of individual method classes in Section 10.3.3.7. The fitness of bias adjustment for climate change applications is assessed in Section 10.3.3.9.

Relevance of bias adjustment
An argument made for the use of bias adjustment is the fact that impact models are commonly very sensitive, often nonlinearly, to the input climatic variables and their biases, in particular when threshold-based climate indices are required (Dosio, 2016). There are, however, cases where bias adjustment may not be necessary or useful, such as: when only qualitative statements are required; when only changes in mean climate are considered (instead of absolute values); when percentile-based indices are used.

Modification of the climate change signal
Bias adjustment methods like quantile mapping can modify simulated climate trends, with impacts on changes to climate indices, in particular, extremes (Haerter et al., 2011; Dosio et al., 2012; Ahmed et al., 2013; Hempel et al., 2013; Maurer and Pierce, 2014; Cannon et al., 2015; Dosio, 2016; Casanueva et al., 2020). Some argue that these trend modifications are implicit corrections of state-dependent biases (Boberg and Christensen, 2012; Gobiet et al., 2015). However, others argue that the modification is generally invalid because the modification is linked to the representation of day-to-day rather than long-term variability (Pierce et al., 2015; Maraun et al., 2017); a given temperature value does not necessarily belong to the same weather state in present and future climate (Maraun et al., 2017); the modification affects the models climate sensitivity (Hempel et al., 2013); and is affected by random internal climate variability (Switanek et al., 2017). Thus, trend preserving quantile mapping methods have been developed (Section 10.3.1.3.2), although some authors found no clear advantage of these methods (Maurer and Pierce, 2014). Further research is required to fully understand the validity of trend modifications by quantile-mapping.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Bias adjustment in the presence of large-scale circulation errors

The large-scale circulation has a strong impact on regional climate, thus circulation errors will cause regional climate biases (Section 10.3.3.3). As bias adjustment in general does not account for circulation errors, it is therefore important to understand the impact of these errors on the outcome of the bias adjustment (Addor et al., 2016; Photiadou et al., 2016; Maraun et al., 2017). If the frequency of precipitation-relevant weather types is biased, a standard bias adjustment (not accounting for this frequency bias) would remove the overall climatological bias, but the precipitation falling in a given weather type could still be substantially biased (Addor et al., 2016). Adjusting the number of wet days can artificially deteriorate the spell-length distribution (Maraun et al., 2017). In the presence of location biases of circulation patterns, bias adjustment may introduce physically implausible solutions (Maraun et al., 2017). Bias adjusting the location of circulation features (Levy et al., 2013) may introduce inconsistencies with the model orography, land-sea contrasts, and SSTs (Maraun et al., 2017).

There is *medium confidence* that the selection of climate models with low biases in the frequency, persistence and location of large-scale atmospheric circulation can reduce negative impacts of bias adjustment.

Using bias adjustment for statistical downscaling

Bias adjustment is often used to downscale climate model results from grid box data to finer resolution or point scale. It is sometimes even directly applied to coarse-resolution global model output to avoid an intermediate dynamical downscaling step (Johnson and Sharma, 2012; Stoner et al., 2013). But bias adjustment does not add any information about the processes acting on un-resolved scales and is therefore by construction not capable of bridging substantial scale gaps (Maraun, 2013a; Maraun et al., 2017). Using bias adjustment for downscaling has been shown to artificially modify long-term trends, misrepresent the spatial characteristics of extreme events, and misrepresent local weather phenomena such as temperature inversions (Maraun, 2013a; Gutmann et al., 2014; Maraun et al., 2017). Crucially, sub-grid influences on the local climate change signal are not represented. For instance, if a mountain chain is not resolved in the driving model, the snow-albedo feedback is not represented by the bias adjustment such that local temperature trends in high altitudes are under-represented (Maraun et al., 2017; Cross-Chapter Box 10.2, Figure 1). It has therefore been suggested to account for local random variability by combining bias adjustment with stochastic downscaling (Volosciuk et al., 2017; Lange, 2019), although this approach still does not account for local modifications of the climate change signal. Two approaches have been proposed to represent these local changes: dynamical downscaling with high-resolution RCMs (Maraun et al., 2017) or statistical emulators of such (Walton et al., 2015). Sections 10.3.3.4–10.3.3.6 and 10.3.3.9 discuss other examples where RCMs improve the representation of regional phenomena and regional climate change.

Overall, there is *high confidence* that the use of bias adjustment for statistical downscaling, in particular to downscale coarse resolution global models, has severe limitations.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Bias adjustment of multiple variables

Impact models, as well as indices of climatic impact-drivers, often require input of several meteorological variables (Chapter 12). In several situations, for example, if the dependence between the variables is not well simulated, univariate bias adjustment of the individual variables may increase biases in the resulting indicator (Zscheischler et al., 2019). A simple alternative would be a bias adjustment of the indicator, but such a procedure may substantially alter the climate change signal, in particular for extreme events (Casanueva et al., 2018). Multivariate bias adjustment methods are in principle good to adjust all statistical aspects of the multivariate distribution that they intend to adjust. Depending on the method, this includes the correlation structure or even broader aspects of the dependence (Cannon, 2016, 2018; Vrac, 2018; François et al., 2020). If multivariate adjustment includes a spatial dimension, then spatial dependence is adjusted well (Vrac, 2018), but care is needed when applied across large areas (François et al., 2020). Adjustment of multivariate dependence necessarily modifies the temporal sequencing of the driving model (Cannon, 2016; Maraun, 2016). The extent of the modification depends on the chosen method and the number of variables to adjust (Vrac and Friederichs, 2015; Cannon, 2016; Vrac, 2018; François et al., 2020).

Bias adjustment in the presence of observational uncertainty and internal variability

Observational uncertainties and internal variability introduce uncertainty in the estimation of biases and thus in the calibration of bias-adjustment methods. Dobor and Hlásny (2018) found a considerable influence of the choice of the observational dataset and calibration period on the adjustment for some regions. RCM biases are typically larger than observational uncertainties, but in some regions, and in particular for wet-day frequencies, spatial patterns and the intensity distribution of daily precipitation, the situation may reverse (Kotlarski et al., 2019). Switanek et al. (2017) found a strong influence of internal variability and thus of the choice of calibration period on the calibration of quantile mapping and on the modification of the climate change signal.

Bias adjustment is typically evaluated using cross-validation, i.e. by calibrating the adjustment function to one period of the observational record, and by evaluating it on a different one. Maraun et al. (2017) and Maraun and Widmann (2018) demonstrated that, in the presence of multi-decadal internal variability, cross-validation may lead to a rejection of a valid bias adjustment or even lead to a positive evaluation of an invalid adjustment. The authors therefore argued that, in the presence of substantial internal variability, the evaluation of bias adjustment requires to consider aspects that have not been adjusted, such as temporal, spatial, or multi-variable dependence.

There is *high confidence* that observational uncertainty and internal variability adversely affect bias adjustment and introduce uncertainties in bias adjusted future projections.

Overall assessment and new avenues

In the light of these issues, several authors dismiss the use of bias adjustment for climate change studies (Vannitsem, 2011; Ehret et al., 2012). Ehret et al. (2012) and Stocker et al. (2015) propose to at least provide the raw model output alongside the adjusted data. Maraun et al. (2017b) argue that the target resolution should be similar to the model resolution to avoid downscaling issues. Stocker et al. (2015) and Maraun et al. (2017) highlighted the relevance of understanding model biases and the misrepresentations of the underlying physical processes prior to any adjustment. Together with Galmarini et al. (2019) , they point out the need for collaboration between bias adjustment users, experts in climate modelling and experts in the considered regional climate. As new research avenues, development of process-oriented bias adjustment methods (Addor et al., 2016; Verfaillie et al., 2017; Manzanas and Gutiérrez, 2019) or run-time bias adjustment integrated into the climate simulation, e.g., to reduce circulation errors (Guldberg et al., 2005; Kharin et al., 2012; Krinner et al., 2019, 2020) are proposed.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.4 Interplay between Anthropogenic Change and Internal Variability at Regional Scales

This section focuses on the assessment of the methodologies used to identify the physical causes of past and future regional climate change in the context of the ongoing anthropogenic influence on the global climate. The main foci are the attribution of past regional-scale changes (Sections 10.4.1–2) and the robustness and future emergence of the regional-scale response to anthropogenic forcing (Section 10.4.3).

In this chapter, regional-scale attribution is defined as the process of evaluating the relative contributions of multiple causal factors (or drivers) to regional climate change (Cross-Working Group Box: Attribution (in Chapter 1); Rosenzweig and Neofotis, 2013; Shepherd, 2019). Attribution at regional scale builds upon the usual definition of attribution used in the AR5 (Hegerl et al., 2010; Cross-Working Group Box 1.1). However, in contrast with global-scale attribution methods where internal variability might be considered as a noise problem (Section 3.2), the preliminary detection step is not always required to perform regional-scale attribution since causal factors of regional climate change may also include internal modes of variability in addition to external natural and anthropogenic forcing. Importantly, regional-scale (or process-based) attribution also seeks to determine the physical processes and uncertainties involved in the causal factor's influence (Cross-Working Group Box: Attribution).

Section 10.4.1 describes regional-scale attribution methodologies and assesses their application to regional changes of temperature and precipitation. Section 10.4.2 presents three illustrative attribution examples that illustrate a number of specific regional-scale challenges and methodological aspects. Section 10.4.3 focuses on methodologies used to assess the robustness and emergence of the regional climate response to anthropogenic forcing. A basic description of future regional climate change for all regions considered in the report (as defined in Section 1.4.5) appears in the Atlas.

10.4.1 Methodologies for Regional Climate Change Attribution

Attribution at sub-continental and regional scales is usually more complicated than at the global scale due to various factors: a larger contribution from internal variability, an increased similarity among the responses to different external forcings leading to a more difficult discrimination of their effects, the importance at regional scale of some omitted forcings in global model simulations, and model biases related to the representation of small-scale phenomena (Zhai et al., 2018). Since AR5 and in addition to standard optimal fingerprint regression-based approaches (Section 3.2.1 and Zhai et al. 2018), several emerging methodologies have been increasingly used for regional-scale climate change attribution. These include several statistical approaches that differ in their use or omission of spatiotemporal covariance information. Dynamical adjustment and pattern recognition techniques fall into the category of spatiotemporal methods while univariate detection and attribution methods rely on single grid-point analysis. Finally, the development, evaluation and use of all these methodologies rely upon the availability of multiple and high-quality observational datasets (Section 10.2) as well as multi-model simulations of the historical period constrained by different external forcing combinations, including single-forcing experiments and single-model initial-condition large ensembles (SMILEs).

10.4.1.1 Optimal fingerprinting methods

Optimal fingerprint regression-based methods have been applied to detection and attribution of mean temperature anthropogenic signal in several regions of the world such as Canada, India, Central Asia, Northern and Western China, Australia, and North Africa (Xu et al., 2015; Li et al., 2017a; Dileepkumar et al., 2018; Wang et al., 2018b; Peng et al., 2019; Wan et al., 2019). The influence of anthropogenic forcing, and in particular that of greenhouse gases (GHGs), is robustly detected in annual and seasonal mean temperatures for all considered regions. Most of the observed regional temperature changes since the mid-twentieth century can only be explained by external forcings, with anthropogenic influence being the dominant factor. GHG increase is found to be the primary factor of the anthropogenic-induced warming while the aerosol forcing leads to a cooling offsetting a fraction of the GHG change (Li et al., 2016b, 2017a).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

While the influence of external natural forcing can often be detected as well, its contribution to observed changes is usually much smaller (Li et al., 2017a; Wan et al., 2019). Temperature detection results are found to be robust to the use of different observational data sets and detection methodologies (Dileepkumar et al., 2018).

Detection of mean precipitation changes caused by human influence is much more difficult, due to a larger role of internal variability at regional to local scales, as well as substantial modelling and observational uncertainty (Wan et al., 2015; Sarojini et al., 2016; Li et al., 2017a). However, multi-decadal precipitation changes due to anthropogenic forcing have been detected for several regions. Ma et al. (2017) show that anthropogenic forcing has strongly contributed to the observed shift of China daily precipitation towards heavy precipitation. The observed weakening of the East Asia summer monsoon, also known as the southern flooding and northern drought pattern has been partially linked to anthropogenic forcing (Section 8.3.2.4.2; Song et al., 2014; Tian et al., 2018; Zhou et al., 2017b). Changes in GHGs lead to increasing precipitation over southern China, whilst changes in anthropogenic aerosols over East Asia are the dominant factors determining drought conditions over northern China (Song et al., 2014; Tian et al., 2018). Based on all-forcing and single-forcing simulation ensembles with a high-resolution model, Delworth and Zeng (2014) found that the observed long-term regional austral autumn and winter rainfall decline over southern and particularly southwest Australia is partially reproduced in response to anthropogenic changes in GHGs and ozone in the atmosphere, whereas anthropogenic aerosols do not contribute to the simulated precipitation decline. In contrast, the observed increase of northwest Australian summertime rainfall since 1950 has been partially attributed to anthropogenic aerosol based on CMIP5 detection and attribution single-forcing simulations (Section 8.3.2.4.6; Dey et al., 2019b, 2019a).

It is noteworthy that these methods require a very significant reduction of spatial and temporal dimensions in order to reliably estimate the covariance matrix of internal variability (an entire region is thus often considered as being only one or a few spatial points that represent the spatial average of the whole region or a few sub-regions; time samples are often 5- or 10-year averages). Finally, model bias is rarely considered in statistical models used in detection and attribution regional studies, while it has been shown to have a strong impact on the stability of detection results and their associated confidence intervals when increasing the spatial dimension (Ribes and Terray, 2013). New statistical methods are emerging to provide some alternative to standard optimal fingerprinting but they have not yet been evaluated and applied at regional scales (Section 3.2.2).

10.4.1.2 Other spatiotemporal statistical methods for isolating regional climate responses to external forcing

The primary objective of any attribution method is to optimally separate the influences of external forcing and internal variability on a global or regional climate record. In a multi-model ensemble context, the estimation of the externally-forced climate response has been typically performed by ensemble averaging of linear trends or regional domain spatial average, thus not taking into account the available and complete space and time covariance information. Since AR5, methods using spatiotemporal information have been further developed and used to improve the separation between external and internal drivers in multiple or single historical climate realizations performed by a given global model.

The typical ensemble size of CMIP historical climate simulations for a given model traditionally ranges between one and ten members, with three often being the default choice. At the regional scale, a simple ensemble average with such sample sizes does not provide robust estimates of the response patterns to external forcing (Maher et al., 2019; Deser et al., 2020). Since AR5, pattern filtering methods such as signal-to-noise maximizing empirical orthogonal functions (Ting et al., 2009) have been shown to improve the identification of forced response patterns when only few model members are available (Wills et al., 2020). Using SMILEs as a test bed, it has been shown that pattern filtering strongly reduces the number of ensemble members needed to estimate the forced response pattern compared to simple ensemble averaging. Pattern filtering allows the identification of low signal-to-noise signals such as the El Niño-like response to volcanic eruptions (Khodri et al., 2017; Wills et al., 2020).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Methods to extract the response to external forcing in an observed or simulated single realization include dynamical adjustment (Smoliak et al., 2015; Deser et al., 2016; Sippel et al., 2019) and time-scale separation methods (DelSole et al., 2011; Wills et al., 2018, 2020). Dynamical adjustment seeks to isolate changes in surface air temperature or precipitation that are due purely to atmospheric circulation changes. The residual can then be analysed and attributed to internal changes in both land or ocean surface conditions and the thermodynamical response to external forcing. Smoliak et al. (2015) performed their dynamical adjustment using partial least squares regression of temperature to remove variations arising from sea-level pressure changes. Deser et al. (2016) used constructed atmospheric circulation analogues and resampling to estimate the dynamical contribution to changes in temperature. Sippel et al. (2019) used machine learning techniques known as regularized linear regression to provide estimates of circulation-induced components of precipitation and temperature variability from global to local scales. It is noteworthy that the dynamical adjustment method by itself cannot account for the component of the forced response associated with circulation changes that project onto atmospheric internal variability. However, this component can be estimated within a model framework by averaging the dynamical contribution across multiple members of a SMILE (Deser et al., 2016).

Dynamical adjustment methods have been used by, for instance, Deser et al. (2016), Saffioti et al. (2016), O'Reilly et al. (2017), Gong et al. (2019), and Guo et al. (2019). Deser et al. (2016) focused on the causes of observed and simulated multi-decadal trends in North American temperature. They demonstrated that the main advantage of this technique is to narrow the spread of temperature trends found by the model ensemble and to bring the dynamically-adjusted observational trend much closer to the forced response estimated by the model ensemble mean. Similar results were obtained by Saffioti et al. (2016) regarding recent observed winter temperature and precipitation trends over Europe. Similarly, O'Reilly et al. (2017) applied dynamical adjustment techniques to more carefully determine the influence of the Atlantic Multi-decadal Variability (AMV; Annex AIV.2.7) on continental climates. Over Europe, summer temperature anomalies induced thermodynamically by the warm phase of the AMV are further reinforced by circulation anomalies; meanwhile, precipitation signals are largely controlled by dynamical responses to the AMV. Based on a partial least-squares approach, Gong et al. (2019) showed that recent winter temperature 30-year trends over northern East Asia are strongly influenced by internal variability linked to decadal changes of the Arctic Oscillation. Using dynamical adjustment purely on precipitation observations, Guo et al. (2019) showed that human influence has led to increased wintertime precipitation across north-eastern North America, as well as a small region of north-western North America, and to an increase in precipitation across much of north-western and north central Eurasia. The latter results confirm previous findings obtained by standard optimal fingerprinting methods (Wan et al., 2015).

Time-scale separation methods such as the low-frequency component analysis and ensemble empirical mode decomposition methods take advantage of the longer time scale associated with anthropogenic external forcing compared to that of most internal modes of variability. The low-frequency component analysis method tries to find low-frequency variability patterns by searching for linear combinations of a moderate number of empirical orthogonal functions that maximize the ratio of low-frequency to total variance. It has first been used to separate internal modes of interannual and decadal variability from slowly varying and externally-forced variability in the Pacific and Atlantic Oceans (Wills et al., 2018, 2019). The methodology has also been applied to patterns of observed surface air temperature to isolate the slow components of observed changes that are consistent with the expected response to anthropogenic greenhouse gas and aerosol forcing (Wills et al., 2020).

The ensemble empirical mode decomposition method (Wu and Huang, 2009; Wilcox et al., 2013; Ji et al., 2014; Qian and Zhou, 2014) decomposes data, such as time series of historical temperature and precipitation, into independent oscillatory modes of decreasing frequency. The last step of the method leaves behind a smooth and low-frequency residual time series. Typically, the nonlinear anthropogenic trend (e.g., of 20th-century temperature) can be reconstructed by summing the long-term mean, the residual, and eventually the lowest-frequency mode to account for a multi-decadal forced signal, for instance associated with anthropogenic aerosol forcing. The ensemble empirical mode decomposition method is an example of a data-driven, non-parametric approach that can be used to directly provide an estimate of the forced response

ACCEPTED VERSION SUBJECT TO FINAL EDITING

without the need for model data (Qian, 2016).

10.4.1.3 Other regional-scale attribution approaches

The univariate detection method does not use spatial pattern information, but compares observed trends in gridded datasets with distributions of trends from ensembles of simulations during the historical period (Knutson et al., 2013; Knutson and Zeng, 2018). The trends arising from simulations constrained by natural forcing-only and all-forcing are compared with distributions of trends purely due to internal variability and derived from long simulations with constant pre-industrial external forcing. Consistency between observed and simulated historical trends is also assessed with statistical tests that can be applied independently over a large number of grid points. The fraction of area over a given region where the change is classified as detectable, attributable, or consistent/inconsistent, is then finally estimated. The method can be viewed as a simple consistency test for both amplitude and pattern of observed versus simulated trends. Its application to CMIP3 and CMIP5 models suggests that 80% of the Earth's surface has a detectable anthropogenic warming signal (Knutson et al., 2013). Regarding regional land precipitation changes over the 1901–2010 and 1951–2010 periods, application of the univariate detection method based on CMIP5 models suggests attributable anthropogenic changes at several locations such as increases over regions of the north-central United States, southern Canada, Europe, and southern South America and decreases over parts of the Mediterranean region, northern tropical Africa and southwestern Australia (Knutson and Zeng, 2018).

Another regional attribution technique is based on the similarity of past changes between observations and one or several simulations of a large ensemble that share the same time evolution for a suggested driver of these changes. Huang et al. (2020) used a perturbed physics ensemble to attribute the drying trend of the Indian monsoon over the latter half of the 20th century to decadal forcing from the Pacific Decadal Variability (PDV; Annex AIV.2.6). The ensemble members predicted different trends in PDV behaviour across the 20th century and the negative precipitation trend was only replicated in those members with a strong negative-to-positive PDV transition across the 1970s, consistent with the observed PDV behaviour (see also the detailed case study in Section 10.6). In a similar manner, Cvijanovic et al. (2017) addressed the possible influence of Arctic sea-ice loss on the North Pacific pressure ridge and, consequently, on south-western United States precipitation. They sampled the uncertainties in selected sea-ice physics parameters to achieve a "low Arctic sea-ice" state in their perturbed simulations. They then compared the latter with control simulations representative of sea-ice conditions at the end of the 20th century to assess changes purely due to sea-ice loss.

New methods aiming to remove underlying model biases before performing detection and attribution, for instance related to precipitation changes, are emerging based on image transformation techniques such as warping (Levy et al., 2014a). By correcting location and seasonal precipitation biases in CMIP5 models, Levy et al. (2014b) showed that the agreement between observed and fingerprint patterns can be improved, further enhancing the ability to attribute observed precipitation changes to external forcings. The improvement mainly relies on the assumption that precipitation changes are tied to the underlying climatology, which has been shown to be a reasonable assumption in regions of the world where intensification of the hydrological cycle is expected (Held and Soden, 2006).

Importantly, evidence that the models employed in regional-scale attribution are fit for purpose is essential in order to estimate the degree of confidence in the attribution results (Section 10.3.3). For example, models need to be evaluated and assessed in their ability to simulate internal variability modes that are known to be important drivers of regional climate change (Sections 3.7 and 10.3.3.3 and Annexes AIV.2 and AIV.3). Models are likely to have different performance in different regions and therefore their evaluation needs to be performed in terms of key physical processes and mechanisms relevant to the climate of the region under consideration (Section 10.3.3).

To conclude, there is *very high confidence* (*robust evidence* and *high agreement*) that the use of diverse and independent attribution methods, multiple model ensemble types and observed datasets strengthens the robustness of results of regional-scale attribution studies. Since AR5, multiple SMILEs have provided an

ACCEPTED VERSION SUBJECT TO FINAL EDITING

adequate testbed for new attribution methodologies aimed at separating forced signals from internal variability in observational records as well as small-size single-model ensembles.

10.4.2 Regional Climate Change Attribution Examples

This section focuses on three illustrative examples that span different regions, time scales, attribution methods, without aiming at being comprehensive. These examples illustrate attribution statements that are based upon multiple lines of evidence, combining multiple observational data sets, different generations and types of models, process understanding and assessment of various sources of uncertainty. Detection and attribution assessments for all AR6 regions and specific variables can be found in the Atlas.

10.4.2.1 The Sahel and West African monsoon drought and recovery

The Sahel, fed by the West African monsoon, has experienced severe decadal rainfall variations (Figure 10.11a). Abundant rainfall in the 1950s–1960s was followed by a large negative trend (Figure 10.11b) until at least the 1980s, over which annual rainfall fell by 20–30% (Hulme, 2001). The subsequent partial recovery (Wang et al., 2020) is more uncertain: rain-gauge studies suggest a return to long-term positive anomalies in the western Sahel in the early 2000s (Panthou et al., 2018), while CHIRPS merged satellite/gauge data show a wetter western Sahel since 1981 (Bichet and Diedhiou, 2018b, 2018a). The recovery has been more significant over the central rather than the western Sahel (Lebel and Ali, 2009; Sanogo et al., 2015; Maidment et al., 2015) and a multiple-gauge record supports a greater recovery to the eastern side (Nicholson et al., 2018). In this attribution example, drivers of the long-term drought and subsequent partial recovery are discussed, including anthropogenic GHG and aerosol emissions, and sea surface temperature (SST) variations that, in part, relate to internal variability. The reader is also referred to assessment in Section 8.3.2.4. We define the Sahel within 10°N–20°N across to 30°E, consistent with the eastern boundary used in Chapter 8, and the rainy season as spanning June to September.

[START FIGURE 10.11 HERE]

Figure 10.11: Attribution of historic precipitation change in the Sahelian West African monsoon during June to September. (a) Time series of CRU TS precipitation anomalies (mm day^{-1}, baseline 1955–1984) in the Sahel box (10°N–20°N, 20°W–30°E) indicated in panel (b) applying the same low-pass filter as that used in Figure 10.10. The two periods used for difference diagnostics are shown in grey columns. (b) Precipitation change (mm day^{-1}) in CRU TS data for 1980–1990 minus 1950–1960 periods. (c) Precipitation difference (mm day^{-1}) between 1.5x and 0.2x historical aerosol emissions scaling factors averaged over 1955–1984 and five ensemble members of HadGEM3 experiments after Shonk et al. (2020). (d) Sahel precipitation anomaly time series (mm day^{-1}, baseline 1955–1984) in CMIP6 for 49 historical simulations with all forcings (red), and thirteen for each of greenhouse gas-only forcing (light blue) and aerosol-only forcing (grey), with a thirteen-point weighted running mean applied (a variant on the binomial filter with weights [1-6-19-42-71-96-106-96-71-42-19-6-1]). The CMIP6 subsample of all forcings matching the individual forcing simulations is also shown (pink). (e) Precipitation linear trend (% per decade) for (left) decline (1955–1984) and (right) recovery periods (1985–2014) for ensemble means and individual CMIP6 historical experiments (including single-forcing) as in panel (d) plus 34 CMIP5 models (dark blue). Box-and-whisker plots show the trend distribution of the three coupled and the d4PDF atmosphere-only SMILEs used throughout Chapter 10 and follow the methodology used in Figure 10.6. The two black crosses represent observational estimates from GPCC and CRU TS. Trends are estimated using ordinary least-squares regression. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.11 HERE]

The role of SST forcing in the rainfall decline is assessed first. Competing mechanisms from equatorial Atlantic SSTs and interhemispheric SST gradients regulate decadal variability in the Sahel (Nicholson,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2013), alternatively explained by tropical warming leading to Sahel drought, while North Atlantic warming promotes increased rainfall (Rodríguez-Fonseca et al., 2015). The SST influence has been formalised in an AMV framework (Giannini et al., 2013; Martin and Thorncroft, 2014; Martin et al., 2014; Park et al., 2015), suggesting that relative North Atlantic SST warming increases the Northern Hemisphere differential warming, enhancing Sahel rainfall. The AMV influence is supported by CMIP5 initialized decadal hindcasts (Gaetani and Mohino, 2013; Mohino et al., 2016; Sheen et al., 2017), which outperform empirical predictions based on persistence. Some caution is needed since the full magnitude of internal variability is not captured in most CMIP5 models, as poor resolution prevents reproduction of AMV teleconnection responses (Vellinga et al., 2016), and the magnitude of AMV-related SST variation may be underestimated in CMIP5 (Section 3.7.7, which also assesses that the AMV may be partially forced). The influence of PDV has been studied to a lesser extent, with the PDV positive phase having a negative impact on Sahel rainfall in combined observational/CMIP5 analysis (Villamayor and Mohino, 2015). The closer match between the observed rainfall declining trend and those in an atmosphere-only SMILE, in which SSTs are matched to observations, compared to three coupled SMILEs in which they are not, suggests that the underlying ocean surface might be essential in driving the decline (Figure 10.11e).

In terms of anthropogenic emissions, regional aerosol emissions from Europe, and to a lesser extent from Asia, have been shown in a global model to weaken Sahel precipitation either through a weakened Saharan heat low or via the Walker circulation (Dong et al., 2014). Greenhouse gases (GHGs) and anthropogenic aerosol can be considered together to control ITCZ position based on temperature asymmetry at the hemispheric scale. GHGs increase Sahel precipitation, while aerosol reduces it (in coupled slab-ocean model experiments by Ackerley et al., 2011 following Biasutti and Giannini, 2006). This effect is stronger when models account for aerosol-cloud interactions (Allen et al., 2015). Perturbed physics GCM ensembles suggests that aerosol emissions were the main driver of observed drying over 1950–1980 (Ackerley et al., 2011), supported by CMIP5 single-forcing experiments (Polson et al., 2014). A coherent drying signal in CMIP5 over the extended 1901–2010 period has also been found, although smaller than the observed trend (Knutson and Zeng, 2018). By applying aerosol scaling factors to the historical period in order to sample the uncertainty in CMIP5 aerosol radiative forcing, Shonk et al. (2020) found differences of 0.5 mm day^{-1} for Gulf of Guinea rainfall between strong and weak aerosol experiments as illustrated in Figure 10.11c, although the drying appears further south than observed due to model bias.

For the partial recovery in West African monsoon and Sahel rainfall since the late 1980s, a detection study using three reanalyses (Cook and Vizy, 2015) shows a connection to increasing Saharan temperatures at a rate 2–4 times greater than the tropical mean, also confirmed by multiple observational and satellite-based data (Zhou and Wang, 2016; Vizy and Cook, 2017) and the review of Cook and Vizy (2019). Reanalyses are also noted to significantly underestimate the Saharan warming (Zhou and Wang, 2016). Saharan warming causes a stronger thermal low and more intense monsoon flow, providing more moisture to the central and eastern Sahel, supported by CMIP5 models (Lavaysse et al., 2016), although not all models capture the observed rainfall/heat low relationship. Sahel rainfall is also incorrectly located in prototype versions of a few CMIP6 models, related to tropospheric temperature biases (Martin et al., 2017). Amplified Saharan warming has increased the wind shear, leading to a tripling of extreme storms since 1982, which may partially explain the recovery (Taylor et al., 2017). Instead, observations, multiple models and SST-sensitivity experiments with atmospheric GCMs have suggested that stronger Mediterranean Sea evaporation enhances low-level moisture convergence to the Sahel, increasing rainfall (Park et al., 2016). Meanwhile, an atmospheric GCM study suggested that GHGs alone (in the absence of SST warming) could cause Sahel rainfall recovery, with an additional role for anthropogenic aerosol (Dong and Sutton, 2015); recent changes in North Atlantic SSTs, although substantial, did not exert a significant impact on the recovery. Large spread in the recovery in a five-member atmospheric GCM ensemble suggests that atmospheric internal variability cannot be discounted (Roehrig et al., 2013).

Consistent timing of the southward ITCZ shift during the decline period in CMIP3 and CMIP5 historical simulations supports the role of external forcing, chiefly anthropogenic aerosol (Hwang et al., 2013). The evolution of the observed decline and recovery is largely followed by the CMIP5 multi-model mean, further supporting the role of external drivers (Giannini and Kaplan, 2019). Updated results from CMIP6 for historical simulations with all and single forcings are represented in Figure 10.11d,e, showing smaller trends

ACCEPTED VERSION SUBJECT TO FINAL EDITING

than those observed. Giannini and Kaplan (2019) attempted to unify the driving mechanisms for decline and recovery based on singular-value decomposition of observed and modelled SSTs. Since the 1950s, tropical warming arising from GHGs and North Atlantic cooling from aerosol led to regional stabilization, suppressing Sahel rainfall. The subsequent reduction in aerosol emissions then led to North Atlantic warming and recovery of Sahel rainfall. Such mechanisms continue into the near-term future in idealised and modified RCP experiments, with scenarios featuring more aggressive reductions in aerosol emissions, or including aerosol-cloud interactions, favouring a greater northward shift of rainfall (Allen, 2015; Westervelt et al., 2017, 2018; Scannell et al., 2019). There is paleoclimate evidence of changes to Sahel rainfall in the past, in particular with enhancement of the West African monsoon during the mid-Holocene. However, the mechanisms governing such a change have been shown to be largely dynamical in nature (D'Agostino et al., 2019), suggesting that the mid-Holocene cannot be used to inform the credibility of changes due to greenhouse warming.

There is *very high confidence* (*robust evidence* and *high agreement*) that patterns of 20th-century ocean and land surface temperature variability have caused the Sahel drought and subsequent recovery by adjusting meridional gradients. There is *high confidence* (*robust evidence* and *medium agreement*) that the changing temperature gradients that perturb the West African monsoon and Sahel rainfall are themselves driven by anthropogenic emissions: warming by GHG emissions was initially restricted to the tropics but suppressed in the North Atlantic due to nearby emissions of sulphate aerosols, leading to a reduction in rainfall. The North Atlantic subsequently warmed following the reduction of aerosol emissions, leading to rainfall recovery.

10.4.2.2 The southeastern South America summer wetting

A positive trend in summer (December to February) precipitation has been detected in multiple observational sources in southeastern South America since the beginning of the 20th century (Gonzalez et al., 2013; Vera and Díaz, 2015; Wu et al., 2016; Zhang et al., 2016; Díaz and Vera, 2017; Saurral et al., 2017). Sedimentary records from the Mar Chiquita lake indicate that the last quarter of the 20th century was wetter than any period during the last 200 years (Piovano et al., 2004). In this attribution example the drivers contributing to the positive trend for the period 1951–2014 are discussed (Figure 10.12a). Precipitation anomalies of CRU TS as well as for the two members of a SMILE with the most negative and positive trends for 1951–2014 are displayed in Figure 10.12b. The trend for 1951–2014 using CRU TS and GPCC is illustrated in Figure 10.12c, and for the region defined by the black quadrilateral, it amounts to 2.8 (CRU TS) – 3.5 (GPCC) mm per month and decade (see black crosses in Figure 10.12d) while the mean summer monthly precipitation for the same period is 104 (CRU TS) –109 (GPCC) mm. The trend is also detectable in daily and monthly extremes (Re and Barros, 2009; Marengo et al., 2010; Penalba and Robledo, 2010; Doyle et al., 2012; Donat et al., 2013; Lorenz et al., 2016).

[START FIGURE 10.12 HERE]

Figure 10.12: Southeastern South America positive mean precipitation trend and its drivers during 1951–2014. (a) Mechanisms that have been suggested to contribute to southeastern South America summer wetting. (b) Time series of austral summer (December to February) precipitation anomalies (%, baseline 1995–2014) over the south-eastern South American region (26.25°S–38.75°S, 56.25°W–66.25°W), black quadrilateral in the first map of panel (c). Black, brown and green lines show low-pass filtered time series for CRU TS, and the members with driest and wettest trends of the MPI-ESM SMILE (between 1951–2014), respectively. The filter is the same as the one used in Figure 10.10. (c) Mean austral summer precipitation spatial linear 1951–2014 trends (mm per month and decade) from CRU TS and GPCC. Trends are estimated using ordinary least squares regression. (d) Distribution of precipitation 1951–2014 trends over southeastern South America from GPCC and CRU TS (black crosses), CMIP6 all-forcing historical (red circles) and MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF SMILEs (grey box-and-whisker plots). Grey squares refer to ensemble mean trends of their respective SMILE and the red circle refers to the CMIP6 multi-model mean. Box-and-whisker plots follow the methodology used in Figure 10.6. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

[END FIGURE 10.12 HERE]

The influence of SST anomalies on southeastern South America precipitation have been studied extensively on interannual to multi-decadal time scales (Paegle and Mo, 2002). The positive phase of El Niño Southern Oscillation (ENSO; Annex AIV.2.3) is related to stronger mean and extreme rainfall over south-eastern South America (Ropelewski and Halpert, 1987; Grimm and Tedeschi, 2009; Robledo et al., 2016). The ENSO influence may be modulated by the PDV (Kayano and Andreoli, 2007; Fernandes and Rodrigues, 2018) and the AMV (Kayano and Capistrano, 2014). PDV and AMV also influence the southeastern South American climate independently of ENSO (Barreiro et al., 2014; Grimm and Saboia, 2015; Robledo et al., 2019). While Pacific SSTs dominate the overall influence of oceanic variability in the region, the Atlantic variability seems to dominate on multi-decadal time scales and has been proposed as a driver for the long-term positive trend (Seager et al., 2010; Barreiro et al., 2014). Based on experiments designed to test how southeastern South America precipitation is modulated by tropical Atlantic SSTs, Seager et al. (2010) showed that cold anomalies in the tropical Atlantic favour wetter conditions by inducing an upper-tropospheric flow towards the equator, which, via advection of vorticity, leads to ascending motion over southeastern South America (Figure 10.12a). Monerie et al. (2019) supported this argument showing a negative relationship between southeastern South America precipitation and the AMV index (Huang et al., 2015) using an atmospheric GCM coupled to an ocean mixed layer model with nudged SSTs.

The positive trend of precipitation has also been attributed to anthropogenic GHG emissions and stratospheric ozone depletion. CMIP5 models only show a positive trend when including anthropogenic forcings (Vera and Díaz, 2015). These results were supported by Knutson and Zeng (2018) based on univariate detection/attribution analysis of annual-mean trends for the 1901–2010 and 1951–2010 periods. However, the main features of summer mean precipitation and variability of South America are still not well represented in all CMIP5 and CMIP6 models (Gulizia and Camilloni, 2015; Díaz and Vera, 2017; Díaz et al., 2020). This motivates the construction of ensembles that exclude the worst performing models (Section 10.3.3.4). The construction of ensembles of CMIP5 historical simulations with realistic representation of precipitation anomalies with opposite sign over southeastern South America and eastern Brazil showed that the trend since the 1950s could be related to changes in precipitation characteristics only when simulations included anthropogenic forcings (Díaz and Vera, 2017). GHG emissions have been related to increased precipitation in southeastern South America through three different mechanisms (Figure 10.12a). First, GHG warming induces a non-zonally uniform pattern of SST warming that includes a warming pattern over the Indian and Pacific Oceans that excites wave responses over South America (Junquas et al., 2013). Zonally uniform SST patterns of warming alone lead to precipitation signals opposite to those observed in an atmospheric GCM (Junquas et al., 2013). Second, GHG radiative forcing drives an expansion of the Hadley cell so that its descending branch moves poleward from the region, generating anomalous ascending motion and precipitation (Zhang et al., 2016b; Saurral et al., 2019). The third mechanism by which increased GHG can contribute to increased precipitation in the region is through a delay of the stratospheric polar vortex breakdown. As depicted in Figure 10.12a, both stratospheric ozone depletion and increased GHGs have contributed to the later breakdown of the polar vortex in recent decades (Ceppi and Shepherd, 2019; McLandress et al., 2010; Wu and Polvani, 2017). Mindlin et al. (2020) developed future atmospheric circulation storylines (Section 10.3.4.2, Box 10.2) for Southern Hemisphere mid-latitudes with the CMIP5 models and found that for southeastern South America summer precipitation, increases are related to the late springtime breakdown of the stratospheric polar vortex. The connecting mechanism is through a lagged southward shift of the jet stream (Saggioro and Shepherd, 2019), which enhances cyclonic activity over the region (Wu and Polvani, 2017).

A common feature among the above discussed studies is that even if GCMs simulate positive trends when forced with GHG and/or stratospheric ozone, these trends are in general smaller than those observed (e.g., CMIP6 trends in red open circles in Figure 10.12d). Díaz et al. (2020) showed that to capture the observed trend a multi-model ensemble of SMILEs is needed. Out of the 12 large ensembles examined (with ensemble size varying in the 16–100 range), only seven simulated the observed trend within their range. This could partly be explained by model biases in mean precipitation and its interannual variability. In the sub-ensemble

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of six models that reproduce reasonably well the observed spatial patterns of mean precipitation and interannual variability, the ensemble mean spread is lower, and the forced response, taken as the multi-model ensemble mean, is slightly more positive than that of the six poorly performing models. The signal to noise ratio, estimated as the ratio of the forced response to the spread due to internal variability, is also slightly higher for the best-performing models, suggesting that selecting the best-performing models may have an influence on both attribution of the observed trend and emergence of the forced response in future (Section 10.4.3).

There is *high confidence* that southeastern South America summer precipitation has increased since the beginning of the 20th century. Since AR5, science has advanced in the identification of the drivers of the precipitation increase in southeastern South America since 1950, including GHG through various mechanisms, stratospheric ozone depletion and Pacific and Atlantic variability. There is *high confidence* that anthropogenic forcing has contributed to the southeastern South America summer precipitation increase since 1950, but *very low confidence* on the relative contribution of each driver to the precipitation increase.

10.4.2.3 The southwestern North America drought

Persistent hydroclimatic drought in southwestern North America remains a much-studied event. Drought is a regular feature of the southwestern North America's climate regime, as can be seen in both the modern record, and through paleoclimate reconstructions (Cook et al., 2010; Woodhouse et al., 2010; Williams et al., 2020), as well as in future climate model projections (Cook et al., 2015a). Since the early 1980s, which were relatively wet in terms of precipitation and streamflow, the region has experienced major multiyear droughts such as the turn-of-the-century drought that lasted from 1999 to 2005, and the most recent and extreme 2012–2014 drought that in certain locations is perhaps unprecedented in the last millennium (Griffin and Anchukaitis, 2014; Robeson, 2015; Section 8.3.1.6). Shorter dry spells also happened between these multiyear droughts making 1980 to present a period with an exceptionally steep trend from wet to dry (Figure 10.13a), leading to strong declines in Rio Grande and Colorado river flows (Lehner et al., 2017b; Udall and Overpeck, 2017). While robust attribution of this trend is complicated by the large natural variability in this region, the 20th century warming has been suggested to increase the chances for hydrological drought periods by lowering runoff efficiency (Woodhouse et al., 2016; Lehner et al., 2017b; Woodhouse and Pederson, 2018) and affecting evapotranspiration (Williams et al., 2020). There is some evidence suggesting that the Last Glacial Maximum, a period of low atmospheric CO_2, ~21 ka ago, has a thermodynamically-driven zonal mean precipitation response similar to that of the current state with relatively high CO_2 levels when compared with the pre-industrial period. Pluvial conditions at that time and a reduction in precipitation from the Last Glacial Maximum to the pre-industrial period are consistent with drying trends for the region in models with GHG concentrations exceeding pre-industrial levels. However, the dominant large-scale drivers responsible for the precipitation changes observed during these two transitions are markedly different: mainly ice sheet retreat and increasing insolation on one hand, increasing GHGs on the other hand. This suggests that the Last Glacial Maximum correspondence is fortuitous which strongly limits its use to capture future hydrological cycle changes (Morrill et al., 2018; Lowry and Morrill, 2019; Section 8.3.2.4.4). Furthermore, the conclusion of the Last Glacial Maximum drying versus wetting seems to strongly depend on the physical property of interest, hydrologic or vegetation indicators (Scheff et al., 2017). Droughts are characterized by deficits in total soil moisture content that can be caused by a combination of decreasing precipitation and warming temperature, which promotes greater evapotranspiration. Regional-scale attribution of the prevalence of southwestern North America drought since 1980 then mostly focuses on the attribution of change in these two variables.

The observed southwestern North America drying fits the narrative of what might happen in response to increasing GHG concentrations due to a poleward expansion of the subtropics, that is conducive to drying trends over subtropical to mid-latitude regions (Hu et al., 2013b; Birner et al., 2014; Lucas et al., 2014). However, several studies based on modern reanalyses and CMIP5 models have recently shown that the current contribution of GHGs to Northern Hemisphere tropical expansion is much smaller than in the Southern Hemisphere and will remain difficult to detect due to large internal variability, even by the end of the 21st century (Section 3.3.3.1; Garfinkel et al., 2015; Allen and Kovilakam, 2017; Grise et al., 2018,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2019). In addition, the widening of the Northern Hemisphere tropical belt exhibits strong seasonality and zonal asymmetry, particularly in autumn and the North Atlantic (Amaya et al., 2018; Grise et al., 2018). Therefore, it seems that the recent Northern Hemisphere tropical expansion results from the interplay of internal and forced modes of tropical width variations and that the forced response has not robustly emerged from internal variability (Section 3.3.3.1; Section 10.4.3).

A second possible causal factor is the role for ocean-forced or internal atmospheric circulation change. Analysis of observed and CMIP5-simulated precipitation indicates that the drought prevalence since 1980 is linked to natural, internal variability in the climate system (Knutson and Zeng, 2018). Based on observations and ensembles of SST-driven atmospheric simulations, Seager and Hoerling (2014) suggested that robust tropical Pacific and tropical North Atlantic forcing drove an important fraction of annual mean precipitation and soil moisture changes and that early 21st century multiyear droughts could be attributed to natural decadal swings in tropical Pacific and North Atlantic SSTs. A cold state of the tropical Pacific would lead by well-established atmospheric teleconnections to anomalous high pressure across the North Pacific and southern North America, favouring a weaker jet stream and a diversion of the Pacific storm track away from the southwest (Delworth et al., 2015; Seager and Ting, 2017). The multiyear drought of 2012–2016 has been linked to the multiyear persistence of anomalously high atmospheric pressure over the north-eastern Pacific Ocean, which deflected the Pacific storm track northward and suppressed regional precipitation during California's rainy season (Swain et al., 2017). Going into more detail, Prein et al. (2016) used an assessment of changing occurrence of weather regimes to judge that changes in the frequency of certain regimes during 1979–2014 have led to a decline in precipitation by about 25%, chiefly related to the prevalence of anticyclonic circulation patterns in the northeast Pacific. Finally, the moderate model performance in representing Pacific SST decadal variability and its remote influence (Section 3.7.6) as well as its change under warming may affect attribution results of observed and future precipitation changes (Seager et al., 2019).

It has also been suggested that the ocean-controlled influence is limited and internal atmospheric variability has to be invoked to fully explain the observed history of drought on decadal time scales (Seager and Hoerling, 2014; Seager and Ting, 2017). From roughly 1980 to the present, the regional climate signals show an interesting mix between forced and internal variability. Lehner et al. (2018) used a dynamical adjustment method and large ensembles of coupled and SST-forced atmospheric experiments to suggest that the observed southwestern North America rainfall decline mainly results from the effects of atmospheric internal variability, which is in part driven by a PDV-related phase shift in Pacific SST around 2000 (Figure 10.13b, c). Based upon four SMILEs (three using a coupled GCM and another one an atmospheric GCM constrained by observed SSTs) and a CMIP6 multi-model suite constrained by observed external forcings, Figure 10.13 shows, in agreement with Lehner et al. (2018), that observed SSTs with their associated atmospheric response are the main drivers of the southwestern North America precipitation decrease during the 1983–2014 period. Once aspects of the internal variability are removed by dynamical adjustment, the observed precipitation-change signal and simulated anthropogenically-forced components look more similar (Lehner et al., 2018).

[START FIGURE 10.13 HERE]

Figure 10.13: Attribution of the southwestern North America precipitation decline during the 1983–2014 period. (a) Water year (October to September) precipitation spatial linear trend (in percent per decade) over North America from 1983 to 2014. Trends are estimated using ordinary least squares. Top row: Observed trends from CRU TS, REGEN, GPCC, and the Global Precipitation Climatology Project (GPCP). Middle row: Driest, mean and wettest trends (relative to the region enclosed in the black quadrilateral, bottom row) from the 100 members of the MPI-ESM coupled SMILE. Bottom row: Driest, mean and wettest trends relative to the above region from the 100 members of the d4PDF atmosphere-only SMILE. (b) Time series of water year precipitation anomalies (%, baseline 1971–2000) over the above south-western North America region for CRU TS (grey bar charts). Black, brown and green lines show low-pass filtered time series for CRU TS, driest and wettest members of the d4PDF SMILE, respectively. The filter is the same as the one used in Figure 10.10. (c) Distribution of south-western region-averaged water-year precipitation 1983–2014 trends (in percent per decade) for observations (CRU TS, REGEN, GPCC and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GPCP, black crosses), CMIP6 all-forcing historical simulations (red circles), the MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF SMILEs (grey box-and-whisker plots). Grey squares refer to ensemble mean trends of their respective SMILE and the red circle refers to the CMIP6 multi-model mean. Box-and-whisker plots follow the methodology used in Figure 10.6. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.13 HERE]

Importantly, as the AR6 assessment views the PDV as being mostly driven by internal variability (Section 3.7.6), the lines of evidence cited above suggest that the contribution of natural and anthropogenic forcings to the precipitation decline has a small amplitude. Unlike the precipitation deficit, the accompanying southwestern North America warming is driven primarily by anthropogenic forcing from GHGs rather than atmospheric circulation variability and may help to enhance the drought through increased evapotranspiration (Knutson et al., 2013; Diffenbaugh et al., 2015; Williams et al., 2015, 2020, Lehner et al., 2018, 2020).

To conclude, there is *high confidence* (*robust evidence* and *medium agreement*) that most (>50%) of the anomalous atmospheric circulation that caused the southwestern North America negative precipitation trend can be attributed to teleconnections arising from tropical Pacific SST variations related to PDV. There is *high confidence* (*robust evidence* and *medium agreement*) that anthropogenic forcing has made a substantial contribution (~50%) to the southwestern North America warming since 1980.

10.4.2.4 Assessment summary

The robustness of regional-scale attribution differs strongly between temperature and precipitation changes. While the influence of anthropogenic forcing on regional temperature long-term change has been detected and attributed in almost all land regions, a robust detection and attribution of human influence on regional precipitation change has not yet fully occurred for many land regions (Section 10.4.3). Although the contribution of anthropogenic forcing to long-term regional precipitation change has been detected in some regions, a robust quantification of the contributions of different drivers remains elusive. The delayed emergence of the anthropogenic precipitation fingerprint with respect to temperature is likely due to the opposing sign of the fast and slow land precipitation forced responses and time-dependent SST change patterns (Section 8.2.1, Section 10.4.3), stronger internal variability (Section 10.3.4.3) as well as larger observational uncertainty (Section 10.2) and impact of model biases. The contribution of internal variability to the observed changes can also be very sensitive to the period length and level of spatial aggregation for the region under scrutiny (Kumar et al., 2016; Cross-Chapter Box 3.1; Section 4.4.1). Finally, even in the case of temperature changes at multi-decadal time scale, internal variability can still be a substantial driver of regional changes due to cancellation between different external forcings (Nath et al., 2018).

To conclude, it is *virtually certain* (*robust evidence* and *high agreement*) that anthropogenic forcing has been a major driver of temperature change since 1950 in many sub-continental regions of the world. There is *high confidence* (*high evidence* and *medium agreement*) that anthropogenic forcing has contributed to multi-decadal mean precipitation changes in several regions such as for example West Africa, southeast South America, southwestern Australia, northern Central Eurasia, South and East Asia. However, at regional scale, the role of internal variability is stronger while uncertainties in observations, models and external forcing are all larger than at the global scale, precluding a robust assessment of the magnitude of the relative contributions of greenhouse gases, including stratospheric ozone, and different aerosol species.

10.4.3 Future Regional Changes: Robustness and Emergence of the Anthropogenic Signal

Regional climate projections are one key element of the multiple lines of evidence that are used for climate risk assessments as well as for adaptation and policy decisions at regional scales (Sections 10.3.3.9 and 10.5). Regional climate projections can be separated into two components: the regional-scale forced response

ACCEPTED VERSION SUBJECT TO FINAL EDITING

or regional-scale climate sensitivity when normalized by the global mean temperature change (Seneviratne and Hauser, 2020) and the climate internal variability characterizing the future period or global warming level under scrutiny. This section assesses a few methodological aspects related to robustness and emergence properties of the regional-scale forced response as well as the possible influence of internal variability on the emergence of the anthropogenic signal.

10.4.3.1 Robustness of the anthropogenic signal at regional scale

Standard methodologies to derive the regional forced response include pattern scaling and the time-shift or epoch approach (Tebaldi and Arblaster, 2014; Vautard et al., 2014; Herger et al., 2015; Tebaldi and Knutti, 2018; Christensen et al., 2019; Section 4.2.4). Pattern scaling assumes that the spatial patterns of regional change, often based on a time-averaged 20 or 30-year period at the end of the 21st century, are roughly constant in time, and simply scale linearly with global mean warming. The time-shift approach defines a target in terms of global warming level (GWL) and locates the time segment, usually 20 or 30 years, in historical or scenario simulations in which global mean warming matches the required GWL (Section 10.1.2; Cross-Chapter Box 11.1). Physical consistency between multiple variables and space-time covariance are fully preserved in the time-shift approach, which is not the case for pattern-scaling (Herger et al., 2015). Importantly, pattern scaling cannot account for the non-linearity arising from either interacting quasi-linear processes (Chadwick and Good, 2013) and purely nonlinear mechanisms, which have been shown to be present in CMIP5 models for high GWL (4°C) and affect precipitation more than temperature at the regional-scale (Good et al., 2015, 2016; Section 8.5.3.1). The time-shift approach can also be used to test whether regional climate change patterns depend on the rate of global mean warming and external forcing pathways, in addition to global warming magnitude. A global evaluation of both approaches in projecting the forced temperature and precipitation response for a highly mitigated scenario based on a moderately mitigated one has been performed using a perfect-model framework (Tebaldi and Knutti, 2018). The amplitude of errors for both approaches appears to be substantially smaller than model uncertainty approximated by the CMIP5 multi-model spread.

Based on large and coordinated modelling exercises such as CMIP5 and CORDEX, the time-shift approach has been largely used to assess differences in regional climate impacts for different GWLs, with a strong focus on 1.5°C versus 2°C (Karmalkar and Bradley, 2017; Dosio and Fischer, 2018; Karnauskas et al., 2018; Liu et al., 2018; Taylor et al., 2018; Weber et al., 2018; Chapter 3, SR1.5, IPCC 2018). Comparisons between pattern scaling and time-shift approaches allow assessment of the scalability of the regional climate change signal and the extent to which pattern scaling assumptions still hold at regional scale for a wide range of GWL. This was the approach followed by Matte et al. (2019) in their assessment of the scalability of European regional climate projections. Based on EURO-CORDEX projections, they performed a detailed comparison between the pattern scaling and the GWL spatial patterns (GWL range: 1°C, 2°C and 3°C) for different seasons, regional model resolutions, and both temperature and precipitation. High pattern correlation values (greater than 0.9) are found between the scaled pattern and all GWL patterns for temperature. In the case of precipitation, the correspondence is slightly lower, especially in summer, for high GWLs (2°C and 3°C) and much lower for 1°C.

Figure 10.14 illustrates a similar comparison based on the CMIP6 multi-model ensemble forced with the scenario SSP5-8.5 and applied to two large-scale continental areas. The forced response to anthropogenic forcing is simply taken as the CMIP6 multi-model mean of future regional climate change relative to the 1850–1900 reference period. Robustness of the forced response is based on both significance of the change and model agreement about the sign of change (Cross-Chapter Box Atlas.1; Figure 10.14). Caution has to be exercised against a too literal interpretation of lack of robust change given that significance and sign agreement can be sensitive to spatial and temporal aggregation (Cross-Chapter Box Atlas.1, Figure 2) and lack of a robust change does not necessarily translate to lack of regional-scale climate change impacts (McSweeney and Jones, 2013; Hibino and Takayabu, 2016).

[START FIGURE 10.14 HERE]

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Figure 10.14: Robustness and scalability of anthropogenic signals at regional scale. (a) Spatial patterns of Europe and Africa summer (June to August) surface air temperature change (in °C °C^{-1}) from the CMIP6 multi-model mean (45 models, one member per model, historical simulations and scenario SSP5-8.5) at different global warming levels (GWLs) and the end-21st century scaling pattern estimated from the multi-model mean difference between 2081–2100 and the pre-industrial period (1850–1900) divided by the corresponding global mean warming. The scale of all GWL patterns has been adjusted to a global mean warming of 1°C (for example, the resulting 3°C spatial pattern has been divided by three). The scales of the GWL patterns have to be multiplied by their threshold values to obtain the actual simulated warming. The metrics shown in the bottom left corner of the GWL pattern plots indicate the spatial pattern correlation and the root-mean square difference between the GWL patterns and the scaling pattern. The number in bold just above the metrics gives the number of used CMIP6 models (out of 45) that have reached the GWL threshold. Areas with robust change (at least 66% of the models have a signal to noise ratio greater than one and 80% or more of the models agree on the sign of the change) are coloured with no pattern overlaid (Cross-Chapter Box Atlas.1). Areas with a significant change (at least 66% of the models have a signal to noise ratio greater than one) and lack of model agreement (meaning that less than 80% of the models agree on the sign of the change) are marked by cross-hatching. Areas with no change or no robust change (less than 66% of the models have a signal to noise ratio greater than one) are marked by negatively sloped hatching. (b) Same as (a) but for North, Central and South America annual mean precipitation relative change (percent °C^{-1}). The baseline for precipitation climatology is 1850–1900. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.14 HERE]

If projected regional mean temperature (Figure 10.14a) and precipitation (Figure 10.14b) changes were to scale linearly with global mean warming, the adjusted spatial patterns would be congruent with each other at different GWLs. While pattern scaling seems to be a reasonable first-order approximation for both temperature and precipitation changes in tropical and high latitude regions (high pattern correlation values), there are a number of regions exhibiting substantial amplitude differences at different GWLs (Northern Africa and Middle East, southern and eastern Europe for temperature; southwestern North America, Chile and north-eastern Brazil for precipitation). These differences hint at the possible influence of nonlinear mechanisms (Good et al., 2015), including soil moisture feedbacks (Seneviratne et al., 2010; Vogel et al., 2017), a time-dependent balance between the different contributions of fast and slow response to greenhouse gas forcing as well as changing SST response patterns (Long et al., 2014; Good et al., 2016; Ceppi et al., 2018; Zappa et al., 2020). Decreasing spatial pattern amplitude with increasing GWL suggests that the initial transient regional response overshoots the long-term change in regions such as northern Africa for summer temperature and southwestern South America for precipitation (Zappa et al., 2020). In the latter region, long simulations with stabilized GHG concentrations even suggest a change of sign when near-equilibrium is reached (Sniderman et al., 2019). The reverse behaviour, increasing pattern amplitude with increasing GWL, is seen for summer temperature in southern and eastern Europe and for precipitation in southwestern North America (Sniderman et al., 2019; Zappa et al., 2020), suggesting that, in these regions, the initial transient response is lagging global mean warming and final regional climate change will be reached once GHG concentrations are stabilized.

There is *high confidence* that the time-evolving contribution of different mechanisms operating at different time scales can modify the amplitude of the regional-scale response of temperature, and both the amplitude and sign of the regional-scale response of precipitation, to anthropogenic forcing. These mechanisms include non-linear temperature, precipitation and soil moisture feedbacks, and slow and fast response of SST patterns and atmospheric circulation changes to increasing GHGs.

10.4.3.2 Emergence of the anthropogenic signal at regional scale

This section provides an assessment of the different approaches used in emergence studies as well as sensitivities to methodological choices. The section then focuses on the possible influence of internal

ACCEPTED VERSION SUBJECT TO FINAL EDITING

variability on future emergence of the simulated mean precipitation anthropogenic signal at regional scales with some illustrative examples.

In climate science, emergence or distinguishability of a signal refers to the appearance of a persistent change in the probability distribution and/or temporal properties of a climate variable compared with that of a reference period (Giorgi and Bi, 2009; Mahlstein et al., 2011, 2012; Hawkins and Sutton, 2012; Section 1.4.2). Similar to anthropogenic climate change detection (Cross-Working Group Box: Attribution (in Chapter 1)), signal emergence can be detected, at least initially, without identifying the physical causes of the emergence (Section 1.4.2). In the context of human influence on climate, the objective of emergence studies is the search for the appearance of a signal characterizing an anthropogenically-forced change relatively to the climate variability of a reference period, defined as the noise.

Precise definitions of signal and noise as well as a metric to measure the relative importance of the signal are key ingredients of the emergence framework and depend on the framing question. In particular, emergence study results can depend on the specific definitions of signal and noise such as the level of spatial and temporal aggregation (McSweeney and Jones, 2013). For instance, grid-point scale emergence will likely be delayed compared with region-average emergence (Fischer et al., 2013; Maraun, 2013; Lehner et al., 2017a; Section 11.2.4; Cross-Chapter Box Atlas.1, Figure 2). The signal is often estimated by a running mean multi-decadal average or probability distribution function of the physical variable under scrutiny in order to avoid false emergence due to manifestation of multi-decadal internal variability (King et al., 2015). In the case of extremes such as climate records, a notion of multi-year persistence or recurrence can also be used to fully characterize the anthropogenic signal and its emergence (Christiansen, 2013; Bador et al., 2016).

Emergence is also sensitive to the noise characteristics: assuming a common signal definition, larger signal-to-noise values and earlier emergence will arise if the noise is based on decadal mean variability rather than interannual variability (Kusunoki et al., 2020). Depending on the framing question, the noise can include or omit external natural forcing such as volcanic and solar forcing (Zhang and Delworth, 2018; Silvy et al., 2020). Furthermore, emergence results are very sensitive to the choice and length of the reference period (Section 1.4.1). The reference period can be the pre-industrial, the very recent past or even a time-evolving baseline, depending on both the framing and assumption that adaptation to the current climate has already occurred (King et al., 2015; Zhang and Delworth, 2018; Brouillet and Joussaume, 2020). These choices will then determine the type of simulations and periods that will be used to construct the noise distribution. Finally, the permanence of future emergence cannot be taken for granted when emergence occurs in the late-21st century based on simulations ending in 2100 (Hawkins et al., 2014; King et al., 2015; Lehner et al., 2017a).

Robust assessments and comparisons of past emergence between observations and models are strengthened by the use of consistent definitions of signal and noise (Lehner et al., 2017a; Hawkins et al., 2020). In the case of future emergence under increasing greenhouse gas emissions, two main approaches have been followed to assess emergence. The first is based on estimating the signal and noise (and sometimes the signal-to-noise ratio as well) in individual models before using the resulting distribution median or mean to construct the final emergence metric (Hawkins and Sutton, 2012; Maraun, 2013b; Sui et al., 2014; Barrow and Sauchyn, 2019). The second method first estimates the signal as a multi-model mean change and the noise variance as a combination of internal variability and model structural differences (Giorgi and Bi, 2009; Mariotti et al., 2015; Nguyen et al., 2018). The first approach allows the definition of emergence of the signal relative to internal variability only and treats model error as source of uncertainty (Maraun, 2013b; Lehner et al., 2017a). The second assumes that the multi-model mean is the optimal estimate of the signal and confounds internal variability and model structural differences in the noise estimate. It is noteworthy that most emergence studies implicitly assume model independence (Annan and Hargreaves, 2017; Boé, 2018; Box 4.1) and therefore sensitivity of emergence results to model selection or weighting is rarely performed (Akhter et al., 2018).

Metrics can vary from a simple signal-to-noise ratio to statistical distributional tests (King et al., 2015; Gaetani et al., 2020) and give median estimates and uncertainty bounds for the date (or time of emergence) corresponding to the exceedance of specific thresholds by the emergence metric. Reconciling future

ACCEPTED VERSION SUBJECT TO FINAL EDITING

emergence results among different studies is challenging due to their many methodological differences including the choice of the reference period, the selected climate models and scenario, the precise definition of signal and noise and the choice of different signal-to-noise thresholds to characterize robust emergence. Contrasting with binary yes/no statements, emergence can also be viewed as a continuous process characterized by an amplitude or level, for example the value of the signal-to-noise ratio, that is a function of time or global warming level.

Since AR5, the development and production of SMILEs (Sections 4.2.5 and 10.3.4.3) has allowed the assessment of the influence of internal variability on anthropogenic signal emergence. The influence of internal variability, and specifically of the unforced atmospheric circulation, on temperature signal emergence can delay or advance the time of emergence by a decade or two in mid-to-high latitude regions (Lehner et al., 2017a; Koenigk et al., 2020). Internal variability can also result in small or decreasing decadal to multi-decadal heatwave frequency trends under the historical anthropogenic forcing over most regions, thereby delaying emergence of unprecedented heatwave frequency trends relative to the pre-industrial trend distribution (Perkins-Kirkpatrick et al., 2017; Sections 11.2–3).

Regional precipitation future changes are much more impacted by internal variability than their temperature counterpart (Monerie et al., 2017b; Singh and AchutaRao, 2018; Dai and Bloecker, 2019; von Trentini et al., 2019; Koenigk et al., 2020). Relative to mean temperature changes, this larger influence of internal variability on mean precipitation changes contributes, among other factors (Sarojini et al., 2016), to a much delayed emergence of the forced precipitation response in observations (Hawkins et al., 2020). Based on the CMIP6 multi-model ensemble forced with the scenario SSP5-8.5, we assess the future emergence of mean precipitation forced change as a function of GWLs for all AR6 land regions (Figure 10.15a). The methodology is a straightforward adaptation of the standard approach (Hawkins and Sutton, 2012). While the standard method is only based on the signal-to-noise ratio exceedance of a specified threshold (taken as one), the approach used here assumes that grid-point emergence occurs when the forced change is considered robust following the AR6 WGI1 definition of robustness for projected changes (Cross-Chapter Box Atlas.1). At a GWL of 1°C, emergence only occurs in high-latitude regions (Wan et al., 2015; Guo et al., 2019b), albeit with only small (less than 30%) area fraction with robust change. Robust changes in tropical and subtropical regions only appear from GWLs of 1.5°C, for example in southwest South America (Boisier et al., 2016), western Africa (Hawkins et al., 2020; Section 10.4.2.1) and southern Australia (Delworth and Zeng, 2014). Substantial (taken here simply as area fraction greater than 50%) emergence only occurs in some tropical, subtropical and midlatitude regions when high GWLs (3°C–4°C) are reached. Importantly, even at these high GWL values, there are still a large number of these regions with robust changes covering less than 50% of their area. In contrast, most high-latitude regions have an area fraction with robust changes greater than 80% at GWLs of 3°C and above.

[START FIGURE 10.15 HERE]

Figure 10.15: Future emergence of anthropogenic signal at regional scale. (a) Percentage area of land regions with robust annual mean precipitation change as a function of increasing GWLs. Robustness of the precipitation change is first estimated at each grid-point followed by the estimation of the AR6 region area with robust changes. For each CMIP6 model considered (45 models, one member per model, historical simulations and scenario SSP5-8.5), the annual mean precipitation change is based on the difference between a 20-year average centred on the GWL crossing year and the mean precipitation during the pre-industrial period (1850–1900) taken as a reference. Robustness of the change is acted when at least 66% of the models (30 out of 45) have a signal to noise ratio greater than one and at least 80% of them (36 out of 45) agree on the sign of change. The signal to noise ratio is estimated for each model from the ratio between the change and the standard deviation of non-overlapping 20-year means of the corresponding pre-industrial simulation (scaled by square root of 2 times 1.645). (b) Time evolution of the percentage area of land region with robust annual mean precipitation change for five AR6 land regions. Thick solid lines represent precipitation changes based on the same CMIP6 ensemble as in (a). Thin solid, dotted and dashed lines represent changes based on the three coupled SMILEs used in Chapter 10, illustrating the influence of internal variability on the emergence of robust change. The change is estimated from the difference between all consecutive 20-year periods from 1900–1919 up to 2081–2100

ACCEPTED VERSION SUBJECT TO FINAL EDITING

and the pre-industrial period. The line colour indicates the sign of the robust change given by the multi-model mean (CMIP6) or ensemble mean (SMILE) change: brown (decreasing precipitation) and dark green (increasing precipitation). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.15 HERE]

We now illustrate the potential influence of internal variability on late or lack of emergence for a few AR6 land regions (Figure 10.15b). For each of these AR6 regions, the time evolution of the percentage area with robust annual mean precipitation change is estimated for both the CMIP6 multi-model ensemble and the three coupled SMILEs used throughout Chapter 10. Similarity in percentage area time evolution between CMIP6 and the three coupled SMILEs suggests that internal variability can substantially influence the timing of emergence. For example, internal variability could explain the mid-21st century emergence (percentage area greater than 50%) of the drying and wetting signal over the Mediterranean and South Asia (see also Section 10.6.3) regions, respectively. Internal variability can also contribute to the late and moderate emergence over southeast South America (see also Section 10.4.2) and western South Africa (see also Section 10.6.2). In contrast, it cannot explain the lack of robust changes (percentage area less than 30%) over western Africa at the end of the 21st century, suggesting that model differences are also contributing to the lack of emergence (Monerie et al., 2017b, 2017a). In addition to different forced signals, the differences of time evolution between the three SMILEs, in particular for African regions, point to the issue of global model performance in accurately representing internal variability and its future changes. While overestimation and underestimation of internal variability in current models have been reported (Eade et al., 2014; Laepple and Huybers, 2014), methodological challenges to assess the magnitude and spatial pattern of model biases in simulating internal variability, still remain (Section 10.3.4.3). Therefore, the existence of model biases and the limited knowledge of their characteristics lead to limitations about a precise quantification of internal variability influence on delayed regional-scale emergence.

There is *high confidence* that consistency in definitions of signal and noise, choice of the reference period and signal-to-noise threshold, is important to robustly assess the future emergence of anthropogenic signals across different types or generations of models, as well as comparing past emergence results between observations and models. There is *high confidence* that internal variability can delay the emergence of the regional-scale mean precipitation anthropogenic signal in many regions, mainly located in the tropics, subtropics and midlatitudes. An accurate estimation of the delay in regional-scale emergence caused by internal variability remains challenging due to global model biases in their representation of internal variability as well as methodological difficulties to precisely estimate these biases (*high confidence*).

10.5 Combining Approaches to Constructing Regional Climate Information

This section assesses approaches and challenges for producing climate information for climate risk assessments as well as for adaptation and policy decisions at regional scales (Section 10.1.2.1). An overview of the different sources used for developing regional climate information is given in Section 10.5.1. The role of the user context in the construction of climate information is assessed in Section 10.5.2. The distillation to combine multiple lines of evidence is assessed in Section 10.5.3. Finally, climate services in the context of regional climate information are assessed in Section 10.5.4. The role of storylines in constructing climate information is assessed in Box 10.2. The assessment of how regional climate information is distilled in the report is treated in Cross-Chapter Box 10.3, whereas the assessment of information on regional, physical climate processes that impact society or ecosystems, termed climatic impact-drivers (Section 10.1), appears in Chapter 12, as well as more information on climate services in Cross-Chapter Box 12.2.

The rise in demand for relevant regional climate information (Hewitt et al., 2012, 2020; Lourenço et al., 2016) has resulted in diverse approaches to produce it. Historically, the construction of climate information has been embedded in a linear supply chain: extracting the source data, processing into maps or derived data products, preparing the material for communication, and delivering to users (Section 10.1.4). Typical

ACCEPTED VERSION SUBJECT TO FINAL EDITING

products are open-access, web-portal delivery services of data (Hewitson et al., 2017), which may also be implemented as commercialised climate services (Webber and Donner, 2017). Such a chain, although it is intended to meet a demand for regional climate information, contains many assumptions that are not obvious to the recipients and that may introduce possible misunderstandings in the hand-over from one community to the next (Meinke et al., 2006; Lemos et al., 2012). In recognition that data is not necessarily relevant information, a new pathway towards a tailored distillation of climate information has emerged. The construction of information assessed in this section draws on multiple sources (Figure 10.16), whereby the context framing for an application is addressed through co-design with users. The constructed information is then translated into the context of the user taking into account the values of all actors involved (Figure 10.1 and Sections 10.5.2 and 10.5.3).

10.5.1 Sources of Regional Climate Information

[START FIGURE 10.16 HERE]

Figure 10.16: Illustration of how using different sources can result in different and potentially conflicting information. Change in daily precipitation (2071–2100 RCP8.5 relative to 1981–2010) over West Africa as simulated by an ensemble of GCM-driven RCMs. (a) Change in daily precipitation (mm) for April to September, as mean of 17 CORDEX models (Dosio et al., 2020) (b-e) Time-latitude diagram of daily precipitation change for four selected RCM-GCM combinations. For each month and latitude, model results are zonally averaged between 10°W–10°E (blue box in a). Different GCM-RCM combinations can produce substantially different and contrasting results, when the same RCM is used to downscale different GCMs (b, d), or the same GCM is downscaled by different RCMs (d, e). GCM1=IPSL-IPSL-CM5A, GCM2=ICHEC-EC-EARTH, RCM1=RCA4, RCM2=REMO2009. Adapted from (Dosio et al., 2020), CCBY4.0 https://creativecommons.org/licenses/by/4.0/. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.16 HERE]

Regional climate information may be constructed from a diverse range of sources, each depending on different assumptions and affected by different methodological limitations (Sections 10.2, 10.3 and 10.4). The construction of information may lead to products for direct adoption by users, or intermediate products for further analysis by users and climate services agencies in collaboration with climate scientists. Widely used sources include:

- Extrapolation of observed historical trends into the future (e.g., Livezey et al., 2007; Laaha et al., 2016). Given that internal variability can affect regional trends significantly on decadal to multidecadal time scales (Section 10.4), this approach could be potentially misleading without other supporting evidence (Westra et al., 2010), or finding congruence with other changes (e.g., Langodan et al., 2020).
- The output from global climate models (GCMs, Section 10.3.1), including high-resolution GCMs, for which performance has been assessed and documented (Section 10.3.3). Model data can be used in its raw form or may be bias adjusted (Section 10.3.1 and Cross-Chapter Box 10.2) or weighted (Section 10.3.4 and Box 4.1).
- The output from dynamically (10.3.1.2) or statistically (10.3.1.3) downscaled GCM simulations for which performance has been assessed and documented as trustworthy (Section 10.3.3). Model data can be used in its raw form or may be bias adjusted, in the case of regional climate models (RCMs, Section 10.3.1).
- Process understanding about climate and the drivers of regional climate variability and change, grounded in theory about dynamics, thermodynamics and other physics of the climate system as a basis for process-based evaluation. For instance, teleconnections are useful to understand the links between large and regional scales at both near and long-term depending on the application. (Sections 10.1.3, 10.3.3, 10.4.1, 10.4.3 and Annex IV).
- Idealized scenarios of possible future climates as narratives to explore the implications and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

consequences of such scenarios in the presence of uncertainty (Jack et al., 2021). This approach has been used to explore the response to geoengineering (Cao et al., 2016), as well as alternative scenarios where model projections are highly uncertain (Brown et al., 2016; Jack et al., 2021).

- Information directly from research reported in the peer-reviewed scientific literature (e.g, Sanderson et al., 2017) or related research reports such as communications to the UN Framework on Climate Change (UNFCCC) about national adaptation.
- Engaging with climate scientists and local communities who may provide indigenous information (Makondo and Thomas, 2018; Rosenzweig and Neofotis, 2013).
- Relevant information may also be drawn from paleoclimate studies (e.g., McGregor, 2018; Armstrong et al., 2020; Kiem et al., 2020) to support and contextualize other sources about more recent and projected changes.

Different sources of information may be more appropriate for some purposes than others, as they may provide information better aligned to the spatial and temporal scales of interest, in different formats, and tailored to different types of application. In some cases, a purpose may be best served using several types of information together. For example, when model data is the primary source, it can be advantageous to employ data from multiple models or even from a range of different experiment types (Section 10.3.2) supported by assessing how the models reflect changes in driving processes. In this manner a purpose may be best served by seeking the congruence of several types of information together, though one needs to recognize how well the attributes of each source align with the specific need for information. Depending on resources, one may even design model experiments specifically for a given use, such as constructing physical climate storylines of individual events (Box 10.2 and Section 10.3.2). Such analyses may be complemented by event attribution studies (Section 11.1.4).

Users of climate information may face the so-called practitioner's dilemma: a plethora of different and potentially contrasting sources (Figure 10.16) may be available without a comprehensive and user-relevant evaluation, and these datasets may also lack a transparent and easily understandable explanation of underlying assumptions, strengths and limitations (Barsugli et al., 2013; Hewitson et al., 2017). Often, the choice of information source is therefore not determined by what is most relevant and informative for the question at hand, but rather by practical constraints such as accessibility and ease of use and may be limited to the availability of just one source in extreme cases (Rössler et al., 2019a).

10.5.2 Framing Elements for Constructing User-Relevant Information

10.5.2.1 Consideration of different contexts

Without considering the specific context, the distillation of climate information relevant to users may poorly serve the goal of informing adaptation and policy (Cash et al., 2003; Lemos et al., 2012; Baztan et al., 2017). Section 10.1.4 identifies three implicit framing issues of constructing and delivering user-relevant climate information: practical issues arising from the climate information sources, issues with including the context in constructing the information, and difficulties presented by complex networks of practitioners. The social context strongly influences decisions about constructing information and requires a nuanced and holistic approach to recognize the complexity of a coupled social and physical system (Daron et al., 2014). For example, urban water managers must recognize the dependency of the city on different water resources and the interplay of both local and national government legislation that can involve a range of different constituencies and decision makers (Scott et al., 2018; Savelli et al., 2021).

Context plays a role in determining the risks that may affect human systems and ecosystems and consequently the climate information needs. The context may also limit access to such information. Hence, the context imposes inherent constraints on how climate information can be constructed and optimally aligned with its intended application. Although contexts are unlimited in variety, some key contextual elements include:

- Whether the problem formulation needs to be constructed through consultative activities that, for instance, help identify thresholds of vulnerability in complex urban or rural systems (Baztan et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2017; Willyard et al., 2018) or is more a matter of addressing a generic vulnerability already identified, such as the frequency of flood events or recurrence intervals of multi-year droughts (Hallegatte et al., 2013).

- Societal capacity, such as cultural or institutional flexibility and willingness to respond to different scientific information (e.g., Hart and Nisbet, 2012; Kahan, 2012, 2013).
- The technical capability and expertise of the different actors, including users, producers, and communicators (e.g., Sarewitz, 2004; Gorddard et al., 2016).
- Potential contrasts in value systems such as the different views of the Global North compared to those of economies in transition or under development (Henrich et al., 2010a, 2010b; Sapiains et al., 2020).
- The relative importance of climate change in relation to non-climate stressors on the temporal and spatial scales of interest to the user, which at times are not the ones initially assumed by the producers (Otto et al., 2015).
- Availability, timing and accessibility of the required climate information, including the availability of sources such as observations, model simulations, literature and experts of the relevant regional climate (Mulwa et al., 2017). In developing countries, the availability of all or some of these sources may be limited (Dinku et al., 2014).

These and other contextual elements can frame subsequent decisions about the construction of regional climate information for applications. For example, an engineer typically seeks quantitative information, while the policy community may be more responsive to storylines and how information is positioned within a causal network describing regional climate risk (Section 1.4.4 and Box 10.2). Multiple contexts can coexist and potentially result in competing approaches (for example, when urban governance contends with regional water-resource management in the same area).

10.5.2.2 Developing climate information conditioned by values of different actors and communities

Developing climate information relevant to user needs can be influenced by the explicit and implicit values of all parties: those constructing the information, those communicating the information, those receiving the information, and, critically, those who construct the problem statement being addressed. A discussion of how values in the scientific community shape climate research appears in Section 1.2.3.2. The influence of values need not be a source of bias or distortion; it is sometimes appropriate and beneficial: critical scrutiny from a diverse range of value-governing perspectives may uncover and challenge biases and omissions in the information that might otherwise go unrecognized (Longino, 2004). Dialogue among all parties in a culturally, socially, and economically heterogeneous society is therefore important for recognizing and reconciling value differences to best yield information that is salient, relevant and avoids ambiguity, most notably when informing the complexity of risks and resilience for human systems and ecosystems in developing nations (e.g., Baztan et al., 2017).

Thus, a challenge with constructing climate information for users, especially about impactful change, is that producing the information may need to involve people with a variety of backgrounds, who have different sets of experiences, capabilities, and values. The information thus would need to accommodate and be relevant to a range of different ways of viewing the problem (Sarewitz, 2004; Rosenzweig and Neofotis, 2013; Gorddard et al., 2016). Failure to recognize the variety of people using the climate information can make it ineffective, even if the source data on which it is based is of the highest quality, and may create a danger of mal-adaptation.

[START FIGURE 10.17 HERE]

Figure 10.17: **Effective regional climate information requires shared development of actionable information that engages all parties involved and the values that guide their engagement.** Participants in the development of climate information come from varying perspectives, based in part on their professions and communities. Each of the three broad categories shown in the Venn diagram (Users,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Producers, Scientists) is not a homogenous group, and often has a diversity of perspectives, values and interests among its members. The subheadings in each category are illustrative and not all-inclusive. The arrows connecting those categories represent the distillation process of providing context and sharing climate relevant information. The arrows that point toward the centre represent the distillation of climate information that involves all three categories.

[END FIGURE 10.17 HERE]

A substantial body of evidence shows that the receptivity of individuals to climate information is strongly conditioned by motivated reasoning (Hart and Nisbet, 2012; Kahan, 2012, 2013), wherein a person's reception of climate information is influenced by the values of the community with which the person identifies. Adherence to a community's values forms part of an individual's social identity (Hart and Nisbet, 2012). Individuals thus frame their analysis and understanding of climate information in the context of cultural values espoused by their community (Hart and Nisbet, 2012; Kahan, 2012, 2013; Campbell and Kay, 2014; Bessette et al., 2017; Tschakert et al., 2017; Vezér et al., 2018). Successful framing of climate information products thus seeks to identify common ground with users, taking account of their values and interests.

Given the relevance of both context and values, the effectiveness of climate information can increase if developed in partnership with the target communities (Tschakert et al., 2016; Figure 10.17). Such an approach can inspire trust among all parties and at the same time promote a co-production process (Cash et al., 2003). Recipients of information have the greatest trust when the communicator is perceived as understanding their context and sharing their values and identity (Corner et al., 2014). As a consequence, developing mental models informed by user values can help with understanding complex climate models and their outcomes (Bessette et al., 2017).

The importance of a co-production process does not preclude the climate-research community from taking steps to develop and convey relevant information on its own. Indeed, communicating expert consensus about contested scientific issues is beneficial (Goldberg et al., 2019). Climate services (Section 10.5.4), in particular, can become effective means for using sources from the climate community and crafting these to be consistent with the needs, interests and values of stakeholder communities. However, simply presenting more information without recognizing user values and the contextual elements listed in Section 10.5.2.1 may be ineffective (Kahan, 2013). An aversion to climate information discordant with one's preexisting beliefs can actually become stronger for people who are more scientifically literate: they feel more confident sifting through all sources of information to find support for their positions (Kahan, 2012). A challenge is that if climate information is not framed carefully, recognizing context and user values, it may make the sceptical person less receptive to further information about climate change (Corner et al., 2012; Hart and Nisbet, 2012; Shalev, 2015). A further complication is that audiences may view climate change as a problem distant in time and space (Spence et al., 2012), too threatening to acknowledge (Brügger et al., 2015; McDonald et al., 2015), or too economically challenging to accept (Bessette et al., 2017). Identifying positive outcomes that align with user values, instead of adaptation and mitigation efforts, appears to promote the interest in and the success of climate information (Bain et al., 2012).

10.5.2.3 The roles of spatial and temporal resolution in relation to decision scale

Climate processes occur on a range of spatial and temporal scales, from global to local, from centuries and longer to days or less (Section 10.1.2 and Figure 10.3). Similarly, decisions by stakeholders cover a range of spatial and temporal scales that can vary with the size of their region of interest and scope of activity. However, the link between decision scales and the spatial and temporal resolution of climate and related non-climatic, natural-system information is not straightforward, and failure to recognize mismatches between the two can undermine the effectiveness and relevance of the information (Cumming et al., 2006; Sayles, 2018).

Nevertheless, the scale of regional climate information does not have to be the same as the decision scale.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Physical-climate storylines (Box 10.2) valid at large scales can be used to develop understanding that is relevant to local decisions. For example, global climate change affecting Antarctic ice-mass loss is relevant to formulating Dutch responses to sea-level rise (Haasnoot et al., 2020). On the other hand, extreme precipitation processes can occur on scales of tens of kilometres and smaller and thus require high resolution climate information when projecting future changes (e.g., Xie et al., 2015). An important factor for developing effective climate information using the distillation process is aligning the vulnerabilities of the social and economic systems under consideration ranging from, for example, those important to a farmer to those important to a national agricultural ministry (Andreassen et al., 2018; O'Higgins et al., 2019). Thus, more sophisticated matching of spatial and temporal resolution of climate information with decision scales requires engagement across a hierarchy of governance structures at national, regional and local level (e.g., Lagabrielle et al., 2018).

10.5.3 Distillation of Climate Information

The preceding sections laid out the diversity of sources of climate information (Section 10.5.1) and important elements for its use in a decision context (Section 10.5.2). Here, it is assessed how context-relevant climate information can be distilled from these sources of information. Although the term distillation lacks a clear definition in the literature, it has, in principle, two aspects: the construction of (potentially user-targeted) information that is defensible and evidence-based (Giorgi, 2020), and the translation of this information into a specific context, targeting a specific purpose and set of values. The former typically involves data from multiple sources, including expert knowledge, and comprehensively considers relevant uncertainties to give physically plausible climate information. The latter translates the information explicitly into the user context, such as by linking it to experience, by formulating a narrative, by highlighting the relevance for the user context, or by putting the climate information into the context of the relevant non-climatic stressors.

Distilling climate information for a specific purpose benefits from a co-production process that includes non-climate-scientists in the research design, analysis and the exploration and interpretation of the results to best place it in context of the intended application (Collins and Ison, 2009; Berkhout et al., 2013; Wildschut, 2017; Bhave et al., 2018; Dessai et al., 2018). Consideration of the specific contexts of information requirements by the provider as well as including the user values in connecting the science with users is increasingly recognized as paramount to construct information relevant for decisions at the regional scale (Section 10.5.2; Kruk et al., 2017; Vizy and Cook, 2017; Djenontin and Meadow, 2018; Parker and Lusk, 2019; Norström et al., 2020; Turnhout et al., 2020). As a response, regional climate change information is increasingly being developed through participatory and context-specific dialogues that bring together producers and users across disciplines and define climate impacts as one of the many stressors shaping user decisions (Brown and Wilby, 2012; Lemos et al., 2012). Although there are multiple practical issues involving communication (Rössler et al., 2019a), such as providing data in a format that users can interpret, being mindful of the contextual issues raised in Section 10.5.2 allows non-scientists to be involved in decisions about approaches and assumptions for the distillation and thus to take ownership of the resultant information and to make informed decisions based on the distilled information (Pettenger, 2016; Verrax, 2017). Importantly, the application of trans-disciplinary engagement processes that emphasise the role of non-scientists in the learning and knowledge production process builds relationships and trust between information users and producers, which is arguably as important for the uptake of climate science into decision making as the nature of the climate information itself (Section 10.5.2).

10.5.3.1 Information construction

Data, either from observations or models, is in general not inherently information, but may contain relevant information if interpreted appropriately (Hewitson et al., 2017). The same applies to other sources of climate information. Relevance is controlled by the given user context (Section 10.5.2.1) and relates to the required temporal and spatial scales (Section 10.5.2.3), the characteristics of required variables (often referred to as indicators), and the meteorological and climatic phenomena driving these variables (Section 10.1.3). For

ACCEPTED VERSION SUBJECT TO FINAL EDITING

example, if climate information for driving impact models is sought (e.g., McSweeney et al., 2015), the impact modelling analysis in the target region is the specific user context.

Climate risk assessment considers all plausible outcomes (Weaver et al., 2017; Marchau et al., 2019; Sutton, 2019). Thus, a key element of information construction is the exploration and reconciliation of different sources of information (Barsugli et al., 2013; Hewitson et al., 2014b; Maraun and Widmann, 2018b) and involves mainly two issues: first, assessing the fitness of different sources in the given context and thereby potentially omitting (or down-weighting) selected sources (Sections 10.3.3), and, second, integrating different sources into a broader picture within a context (Sections 10.3.4).
A non-comprehensive selection of approaches that may contribute to the construction of information includes:

- Overall assessment and inter-comparison of different sources of information, including hierarchies of models and identification of potentially conflicting results (Figure 10.16), where observational availability plays a critical role (Section 10.2.3).
- Assessing the emergence of forced trends from internal variability (Section 10.4.3), and testing whether differences in simulations can be explained by internal variability, ideally using initial-condition large ensembles (Sections 10.3.4.3 and 10.4.3).
- Assessing the interdependence of chosen models to identify the amount of independent information (Section 10.3.4.4).
- Process-based evaluation with focus on those processes that are relevant for the specific application (Sections 10.3.3.4–10.3.3.10).
- Weighting or sub-selecting ensembles based on a priori knowledge or the outcome of a process-based evaluation, while sampling as much uncertainty as possible (Section 10.3.4.4).
- Tracing back differences in projections to the representation of fundamental processes, e.g., by using physical climate storylines (Sections 10.3.4.2 and Box 10.2) or sensitivity simulations (Section 10.3.2.3).
- Producing physical-climate storylines (Box 10.2) to explore uncertainties not sampled by available model ensembles (Shepherd et al., 2018), for example in pseudo-global warming experiments (Section 10.3.2.2), or to simulate events that have never happened before but are nevertheless plausible (Lin and Emanuel, 2016).
- Attributing observed changes to different external forcings and internal drivers (Section 10.4.1).
- Comparing observed trends with past simulated trends in order to constrain projections with, for instance, the Allen-Stott-Kettleborough method (Allen et al., 2000; Stott and Kettleborough, 2002; Stott et al., 2013) to explain drivers of past observed trends (Section 10.4.2) for understanding future trends.
- Integrating present-day performance via emergent constraints to reduce projection uncertainty (Section 10.3.2).
- Complementing the observational and model-based sources with expert judgement (e.g., integrating knowledge from theory or experience that is available from experts or the literature; Section 10.5.1).

These approaches often can be used in combination to increase confidence in conclusions drawn (Hewitson et al., 2017).

10.5.3.2 Translating climate information into the user context

Awareness and understanding of the users' decision-making context is a central and key aspect of developing tailored, context-appropriate information (Briley et al., 2015), as clearly evidenced by the climate services' experiences (e.g., Vincent et al., 2018). Understanding the context, however, is not trivial and requires understanding of both the user and provider (Guido et al., 2020) if the information is to be robust, reliable and relevant (Giorgi, 2020). Translating the information into context requires consideration of terminology and expectations (Briley et al., 2015), issues of user interpretation (Daron et al., 2015), and hence necessitating engagement in co-production with all attendant challenges (Vincent et al., 2021). The actual provision of climate information may be conducted at different levels of sophistication, ranging from

ACCEPTED VERSION SUBJECT TO FINAL EDITING

generic data provision via web portals (Hewitson et al., 2017), potentially including impact-relevant climate indicators, region-specific factsheets and stakeholder reports, social media (Pearce et al., 2019), to a close engagement with specific stakeholders in co-exploring the research (Steynor et al., 2016).

Climate information products may often lack explanations of their potential use and misuse (Street, 2016; Lamb, 2017; Chimani et al., 2020). This is particularly important if the information is provided as a generic, publicly accessible product without a specific context (Hewitson et al., 2017). Context-specific collaboration, especially if organized in workshop, enables a close transdisciplinary co-exploration of the results as in the form of climate risk narratives (Jack et al., 2020, Box 10.2). Such approaches explicitly account for the user context, values and non-climatic stressors (Steynor and Pasquini, 2019).

10.5.3.3 Transdisciplinary approaches to stakeholder interaction

The transdisciplinary interaction with stakeholders has been categorised into top-down, bottom-up and interactive approaches (Berkhout et al., 2013). Traditional top-down approaches frame the research from the perspective of global climate change as a driver of regional climate risk. Bottom-up approaches, also referred to as scenario-neutral impact studies (Prudhomme et al., 2010; Brown et al., 2012a, 2012b; Culley et al., 2016) begin with the user's articulation of vulnerability in the context of climatic and non-climatic stressors, follow with the definition of key system thresholds of climatic variables, and only incorporate climate data to assess the likelihood of threshold exceedances. Bottom-up approaches are special cases of robust decision making (Lempert et al., 2006; Lempert and Collins, 2007; Walker et al., 2013; Weaver et al., 2013), which are designed to account for uncertainties not represented by climate models as well as non-climatic stressors. Interactive approaches combine aspects of top-down and bottom-up approaches. The choice of approach depends on the context. While bottom-up approaches might be optimal in a local context, where case-specific risks are addressed, top-down approaches provide generic information that may serve a range of different purposes, e.g., at the national scale (Berkhout et al., 2013). All these approaches benefit from the integration of fully distilled climate information (Berkhout et al., 2013; Maraun and Widmann, 2018b).

10.5.3.4 Barriers to the distillation of climate information

As implied by Section 10.5.2, meeting the needs of users can be a substantial challenge for climate scientists if they misunderstand or have limited understanding of user needs and context (Porter and Dessai, 2017). Several barriers in user communities can trigger and sustain this challenge. This can include an institutional aversion to incorporating new tools into decision making (Callahan et al., 1999). Coincident with this factor, there may be limited staff capacity, lack of management support and lack of a mandate to plan for climate change (Lee and Whitely Binder, 2010).

Following from those challenges, constructing and communicating regional climate information often occurs under the overarching assumption that uncertainty is a problem and reducing uncertainty is the priority (Eisenack et al., 2014; Otto et al., 2016b). This is both a psychological (Morton et al., 2011) as well as a pragmatic barrier in cases where uncertainty appears to limit the ability to make decisions (Mukheibir and Ziervogel, 2007). However, where in-depth engagements with decision contexts are undertaken, these initial barriers are often dismantled to reveal a more complex, nuanced and potentially more productive intersection with climate information producers that can efficiently handle uncertainty (e.g., Rice et al., 2009; Lemos et al., 2012; Moss, 2016). Specifically, disclosure of all uncertainties in the climate information, transparency about the sources of these uncertainties, and tailoring the uncertainty information to specific decision frameworks have the potential for reducing problems of distilling and communicating uncertain climate information (Otto et al., 2016b).

10.5.3.5 Synthesis assessment of climate information distillation

There is *high confidence* that distilling climate information for a specific purpose benefits from a co-

ACCEPTED VERSION SUBJECT TO FINAL EDITING

production process that involves users of the information, considers the specific user context and the values of relevant actors such as users and scientists, and translates the resultant information into the broader user context. This process allows users to take ownership of the information, builds relationships and trust between information users and producers and helps to overcome barriers in the information construction. This process enhances trust in the information as well its usefulness, relevance, and uptake, especially when the communication involves complex, contextual details (*high confidence*). The optimal approach for the transdisciplinary collaboration with users depends on the specific context conditioned by the sources available and the actors involved, which together are dependent on the regions considered and the framing by the question being addressed.

Drawing upon multiple lines of evidence in the construction of climate information increases the fitness of this information and creates a stronger foundation (*high confidence*). The lines of evidence can include multiple observational datasets, ensembles of different model types, process understanding, expert judgement, and indigenous knowledge, among others. Attribution studies, the characterization of possible outcomes associated with internal variability and a comprehensive assessment of observational, model and forcing uncertainties and possible contradictions using different analysis methods are important elements of distillation. To make the most appropriate decisions and responses to changing climate it is necessary to consider all physically plausible outcomes from multiple lines of evidence, especially in the case when they are contrasting such as in the examples of Cross-Chapter Box 10.1 and Section 10.6.2.

10.5.4 Climate Services and the Construction of Regional Climate Information

Climate services have been defined as the provision of climate information to assist decision-making (Sections 1.2.3, and 12.6, and Cross-Chapter Box 12.2). Services are expected to be based on scientifically credible information and expertise, have appropriate engagement from users and providers, have an effective access mechanism and aim at meeting the users' needs (Hewitt et al., 2020). To achieve this, climate services synthesize context-relevant climate information addressing questions for a wide range of climate time scales. From this point of view, climate services are instruments for the production, translation and transfer of climate information and knowledge for their use in climate-informed decision-making and climate-smart policy and planning (Hewitt et al., 2012). The appropriate provision of climate services considers the diagnosis of climate information needs, the service itself and a number of good practices still under development (Vaughan et al., 2018).

The preceding subsections assess research on the distillation of climate information, which is directly relevant for the development of climate services. Distillation, when implemented appropriately and interpreted with all due caveats, leads to credible climate information with a broader foundation of evidence to be used in climate services practice according to the recommendations of the Global Framework for Climate Services (Hewitt et al., 2012). As stated in Chapter 12, climate services set new scientific challenges to research. Examples of some of the challenges have been given in Chapters 1 and 12, which are complemented by the barriers to the distillation assessed in Section 10.5.3.3.

[START BOX 10.2 HERE]

BOX 10.2: Storylines for constructing and communicating regional climate information

Communicating the full extent of available information on future climate for a region, including an uncertainty quantification, can act as a barrier to the uptake and use of such information (Lemos et al., 2012; Daron et al., 2018). To address the need to simplify and increase the relevance of information for specific contexts, recent studies have adopted storyline and narrative approaches (Hazeleger et al., 2015; Shepherd et al., 2018; Section 1.4.4.2). As such, these approaches are an important tool for the climate information distillation (Section 10.5.3). Here we assess these in a regional climate information context, namely for exploring uncertainties, embedding climate information into a given user context, and communicating climate change information.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Physical climate storylines are self-consistent and plausible unfoldings of a physical trajectory of the climate system, or a weather or climate event, on time scales from hours to multiple decades (Section 1.4.4.2). Storylines that condition climatic features and processes on a set of plausible but distinct large-scale climatic changes enables the exploration of uncertainties in regional climate projections (Box 10.2, Figure 1; Section 10.3.4.2). For instance, Zappa and Shepherd (2017) condition projected changes in European surface wind speeds on different plausible projections of tropical upper tropospheric warming and the polar vortex strength in the CMIP5 multi-model ensemble. Storylines of specific events are generated to explore the unfolding and impacts of comparable events in counterfactual climates (Lackmann, 2015; Meredith et al., 2015b; Takayabu et al., 2015; Hegdahl et al., 2020; Sillmann et al., 2020). Those event storylines can be based on pseudo-global warming studies (Lackmann, 2015; Meredith et al., 2015; Takayabu et al., 2015; Section 10.3.2.2), selected and possibly downscaled events from long-term climate projections (Hegdahl et al., 2020; Huang et al., 2020a), or based on expert judgment of plausible changes to observed events (Pisaric et al., 2011; Dessai et al., 2018). They can be used for attributing events to different causal factors (Lackmann, 2015; Meredith et al., 2015; Takayabu et al., 2015; Trenberth et al., 2015; Shepherd, 2016; Section 11.2.4) as well as for exploring the unfolding of events in future climates.

Physical climate storylines are complementary to probabilistic or unconditional risk-based approaches, and are particularly suitable to explore low-likelihood changes or events, which are often associated with the highest impacts (Shepherd et al., 2018; Sillmann et al., 2020; Section 4.8). They also facilitate providing local context to large-scale trends and changes, by conditioning the projections on locally relevant circumstances (Hazeleger et al., 2015). Storylines are also developed based on expert elicitation and include plausible changes beyond those simulated by existing model projections in order to explore deep uncertainties (Dessai et al., 2018).

Storylines can be combined with impact modelling (Strasser et al., 2019; Hegdahl et al., 2020) and can be embedded in a user's risk landscape (Shepherd, 2019; Box 10.2, Figure 1). This holds in particular for event storylines, where confounding factors such as regional characteristics like land-use changes and non-climatic drivers of the event are an element of the storyline (Pisaric et al., 2011; Dessai et al., 2018; Lloyd and Shepherd, 2020; Sillmann et al., 2020). In a co-production process, multi-disciplinary expert knowledge as well as the values and interests of the intended audiences and stakeholders can be explicitly considered (Kok et al., 2014; Bhave et al., 2018; Dessai et al., 2018; Scott et al., 2018; Hegdahl et al., 2020).

Storylines can also be used to communicate climate information by narrative elements describing the main climatological features and the relevant consequences in the user context (Fløttum and Gjerstad, 2017; Moezzi et al., 2017; Dessai et al., 2018; Scott et al., 2018; Jack et al., 2020). Co-produced narratives have been demonstrated to enhance knowledge integration in decision-making contexts (e.g., de Bruijn et al., 2016). Narrative elements have also been employed to convey information from climate models (Corballis, 2019). Jack et al. (2020) introduced the concept of climate risk narratives and developed a set of principles, such as using present tense in their presentation to avoid effects of future discounting, and writing individual narratives without uncertainty language to assume an imagined observer perspective. From this point of view, event storylines are particularly useful for communication purposes as they link to the experience and episodic memory of stakeholders (Schacter et al., 2007; Steynor et al., 2016; Shepherd et al., 2018).

[START BOX 10.2, FIGURE 1 HERE]

Box 10.2, Figure 1: Schematic of two types of physical climate storylines with a particular climate impact of concern (red). The storylines are defined by specified elements (dark blue). Variable elements (light blue) are simulated conditional on the specified elements. The white elements are 'blocked' since their state does not need to be known to determine the light blue elements. Other types of storylines could be defined by specifying other elements (e.g., storylines of different climate sensitivities or different representative concentration pathways). (a) Event storyline, where the particular dynamical conditions during the event as well as the regional warming are specified and control the hazard arising from the event. (b) Dynamical storyline, where the global warming level and remote drivers are specified and control the long-term changes in atmospheric dynamics and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

regional warming. In both storylines, the impact is also conditioned on specified exposure and vulnerability. Adapted from Shepherd (2019).

[START CROSS-CHAPTER BOX 10.3 HERE]

Cross-Chapter Box 10.3: Assessment of climate change information at the regional scale

Coordinators: Erika Coppola (Italy), Alessandro Dosio (Italy), Friederike Otto (UK/Germany)
Contributors: Claudine Dereczynski (Brazil), Melissa I. Gomis (France/Switzerland), Richard G. Jones (UK), Roshanka Ranasinghe (The Netherlands, Sri Lanka, Australia), Alexander C. Ruane (USA), Sonia I. Seneviratne (Switzerland), Anna A. Sörensson (Argentina), Bart van den Hurk (The Netherlands), Robert Vautard (France), Sergio M. Vicente-Serrano (Spain)

This Cross-Chapter Box illustrates how assessments of past, present and future regional climate changes (e.g., change in an extreme event index or Climatic Impact-Driver, CID) are derived in the WGI report. Robust assessments can be derived when changes are supported by multiple lines of evidence.

Multiple, sometimes contrasting, lines of evidence are derived from the various data sources, methodologies and approaches that can be used to construct climate information (Figure 10.1, Section 10.5). Such data sources and methodologies include theoretical understanding of relevant processes, drivers and feedbacks of climate at regional scale, observed data from multiple datasets (e.g., ground station networks, satellite products, reanalysis, etc.), simulations from different model types (including GCMs, RCMs, statistical downscaling methods, etc.) and experiments (e.g., CMIP5 and 6, CORDEX, and Single-Model Initial-condition Large Ensembles), methodologies to attribute observed changes or events to large- and regional-scale anthropogenic and natural drivers and forcings as well as other relevant local knowledge (e.g., indigenous knowledge).

The assessment is derived following the IPCC uncertainty guidance through a distillation process of multiple lines of evidence on observed trends, attribution of trends or events, climate model projections and physical understanding, covered in several chapters of the WGI report.

In particular, this Cross-Chapter Box explains the methodology used to derive the regional assessments summarised in the Technical Summary (TS) table that are, in turn, used as a basis for the synthesis assessment in the Summary for Policymakers (SPM).

[START CROSS-CHAPTER BOX 10.3, FIGURE 1 HERE]

Cross-Chapter Box 10.3, Figure 1: Schematic illustration of the process to derive the assessment of regional climate change information based on a distillation process of multiple lines of evidence taken from observed trends, attribution of trends or events, climate model projections, and physical understanding.

[END CROSS-CHAPTER BOX 10.3, FIGURE 1 HERE]

The process consists of three discrete steps, listed below and schematically illustrated in Cross-Chapter Box 10.3, Figure 1:

1) Collection and assessment of the fitness for purpose of available information

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Any specific climate change that is regionally relevant is assessed looking at lines of evidence, potentially across multiple indices. For example, several definitions of "drought" exist that refer to a variety of the underlying processes, temporal and spatial scales, as well as sectoral applications and associated impacts (Sections 11.6, 12.3). Such diverse definitions need to be gathered from the relevant literature, compared, and individually assessed if appropriate.

Once the indices of change are properly defined, the relevant climate information is collated from the available sources.

The information is then evaluated against its fitness for purpose, i.e., whether it is adequate to provide robust evidence to derive an assessment. In the case of observed data, issues to be considered include (but are not limited to): spatial and temporal resolution, accuracy, gaps in the recorded data, homogeneity in the station network, uncertainty treatment, etc. (Sections 10.2, 11.2, 11.9, 12.4, Atlas.1.4). In case of modeled data, an assessment of the fitness for purpose typically includes an evaluation of numerical or statistical methods adopted, adequate representation of the physical processes, forcings and feedbacks relevant for the region and the change under consideration, the availability of adequate ensembles to assess the interplay between forced response and internal variability and the uncertainty in future projections (Sections 10.3, 10.4, 11.2, 11.9, 12.4 and Chapter Atlas). Attribution assessments are usually based on models and observations for which the fitness for purpose is assessed with similar criteria as those described above (Cross-Working Group Box: Attribution (in Chapter 1)). The assessment is made either directly or indirectly by scrutinizing the data and methods of the relevant literature against the criteria listed above.

2) Assessment of confidence of the multiple lines of evidence

Once the relevant information has been collated for a given regional change, an assessment of the confidence is first made for each line of evidence separately. The assessment of confidence is the result of expert judgment drawing around a set of questions such as:

- Do we have a physical explanation of the processes responsible for past and future changes in the region?
- Do observed trends agree amongst different observational products/datasets? Are they statistically significant? Do the observations cover the same temporal period and/or spatial area? Are the observations homogeneous in time?
- Can past trends be attributed to human activities (GHGs, SLCFs or land use/management changes)? Are attributed trends and events consistent? What is the interplay between internal variability and forced response?
- Do model projections agree on the magnitude and sign of the projected signal? Are we able to understand the reasons underlying any discrepancies? Can we quantify the uncertainty in the projected signal? Are the projections based on similar SSP-RCP/time horizon or GWL (Cross-Chapter Box 11.1)? If not, are they comparable?
- Has the signal already emerged? Are there studies indicating the time of emergence of the signal?

The assessment is then tested for overall coherence across the available lines of evidence, for example:

- Are observed historical changes consistent with future projections?
- Are attributed events similar to the types of changes projected for the future?
- Is there a physical explanation for changes that are projected but have not yet been clearly observed or attributed?
- Are assessments of confidence and likelihood performed in a similar way across regions?

3) Distillation of regional information and synthesis of the independent assessments

To ensure transparency, a traceback matrix is constructed (refer to 10.SM) that, for each region and index, identifies where in the chapters the relevant information can be found, together with a summary of the relevant information in the Technical Summary.

Based on assessments mainly in Chapters 8, 9 11, 12 and Atlas, the table in Technical Summary TS.4.3.1 collates, by means of colours and symbols, the assessment of the confidence in past trend, attribution and direction of future change. This distillation process is illustrated below with two examples: (1) a relatively

ACCEPTED VERSION SUBJECT TO FINAL EDITING

simple case for the assessment of extreme heat over Southeast South America, where most of the lines of evidence agree, and (2) ecological, agricultural and hydrological drought in the Mediterranean, which is more complex due to the different definitions of 'drought' and the sometimes conflicting information arising from different lines of evidence and the example shown here is preceded by the decision to focus on these types of drought rather than, e.g., meteorological drought.

a) Extreme heat in southeastern South America (SES)

Observed past trends

Mean temperature and extreme maximum and minimum temperatures have shown an increasing trend (*high confidence*). An increase in the intensity and in the frequency of heatwave events between 1961 and 2014 is also observed. However, there is *medium confidence* that warm extremes have decreased in the last decades over the central region of SES during austral summer (Sections Atlas.7.2.2 and 11.9).

There is evidence of increasing heat stress during summertime in much of SES for the period 1973-2012 (Section 12.4.4.1).

Attribution

Based on trend detection and attribution studies of maximum and minimum temperatures and event attribution of heat waves in the region, there is *high confidence* in a human contribution to the observed increase in the intensity and frequency of hot extremes (Section 11.9).

The increasing heat stress over summertime in much of SES has been attributed to human influence on the climate system (Section 12.4.4.1).

Projections

There is *high confidence* that by the end of century most regions in South America will undergo extreme heat stress conditions much more often than in the recent past, with about 50-100 more days per year under SSP1-2.6 and more than 200 additional days per year under SSP5-8.5 (*high confidence*) (Section 12.4.4.1).

Based on different lines of evidence (GCMs, RCMs) an increase in the intensity and frequency of hot extremes is *extremely likely* for SES at all assessed warming levels (compared with pre-industrial) (Section 11.9).

Synthesized assessment in the Technical Summary from multiple lines of evidence

There is *high confidence* that extreme temperatures have increased over SES over the last decades and that human influence *likely* contributed to the observed changes in extreme temperatures. An increase in the frequency and intensity of heatwave events has been observed. Most land regions will frequently undergo extreme heat stress conditions by the end of the 21st century, with an increase in the frequency of heatwaves and heat stress conditions (Technical Summary TS.4.3.2).

b) Mediterranean ecological, agricultural and hydrological droughts

Observed past trends

Hydrological modelling suggests that the recent decline in soil moisture in the Mediterranean is unprecedented in the last 250 years. Paleoclimate evidence extends this view, additionally indicating that dryness in the Mediterranean is approaching an extreme condition compared to the last millennium (Section 8.3.1.6).

There is an increase in probability and intensity of agricultural and ecological droughts (*medium confidence*) and there is an increase in frequency and severity of hydrological droughts (*high confidence*) (Section 11.9).

Attribution

Global warming has contributed to drying in dry summer climates including the Mediterranean (*high confidence*). Records of soil moisture indicate that higher temperatures and increased atmospheric demand have played a strong role in driving Mediterranean aridity. Multiple lines of evidence suggest that anthropogenic forcings are causing increased aridity and drought severity in the Mediterranean region (*high*

ACCEPTED VERSION SUBJECT TO FINAL EDITING

confidence) (Section 8.3.1.6).

An increasing trend towards agricultural and ecological droughts has been attributed to human-induced climate change in the Mediterranean (*medium confidence*). Model-based assessment shows with *medium confidence* a human fingerprint on increased hydrological drought, related to rising temperature and atmospheric demand, and frequency and intensity of recent drought events. There is *medium confidence* that change in land use and terrestrial water management contribute to trends in hydrological drought (Section 11.9).

Projections

There is *high confidence* that drought severity and intensity will increase in the Mediterranean. Increased evapotranspiration due to growing atmospheric water demand will decrease soil moisture (*high confidence*). The seasonality of runoff and streamflow (the annual difference between the wettest and driest months of the year) is expected to increase with global warming (*high confidence*). Annual runoff is very likely to decrease. Under middle or high emissions scenarios, the likelihood of extreme droughts increases by 200–300% in the Mediterranean. The paleoclimate record provides context for these future expected changes: climate change will shift soil moisture outside the range of observed and reconstructed values spanning the last millennium (*high confidence*) (Sections 8.4.1.5 and 8.4.1.6).

There is *medium confidence* in the increase of agricultural and ecological drought at +1.5ºC, *high confidence* at +2ºC and *very likely* at +4ºC, with large decreases in soil water availability during drought events and increase in drought magnitude. There is *medium confidence* in the increase in hydrological drought at +1.5ºC, *high confidence* at +2ºC and *very likely* at +4ºC with very strong decrease (40-60%) of total runoff in the spring-summer half-year and a 50-60% increase in frequency of days under low flow (Section 11.9).

There is *high confidence* that agricultural, ecological and hydrological droughts will increase in the Mediterranean region by mid and far end of century under all RCPs (except RCP2.6/SSP1-2.6), or for GWLs equal to or higher than 2ºC (Section 12.4.5.2).

Synthesized assessment in the Technical Summary from multiple lines of evidence

There is *high confidence* that hydrological droughts have increased in the Mediterranean since the 1960s related to rising temperature and atmospheric demand, and *medium confidence* of a human fingerprint on this increase. There is *medium confidence* in the increase of ecological and agricultural droughts and in their attribution to human-induced climate change. There is *high confidence* of an increase in ecological, agricultural and hydrological droughts for warming levels exceeding 2°C, and *medium confidence* of an increase for lower warming levels (Technical Summary TS4.3.2).

[END CROSS-CHAPTER BOX 10.3 HERE]

10.6 Comprehensive Examples of Steps Toward Constructing Regional Climate Information

10.6.1 Introduction

This section presents three comprehensive examples of steps for distilling regional climate information from the multiple sources of regional climate information presented in this chapter. These examples build on the general framework presented in Section 10.5, examining in particular the strengths and challenges in linking the different sources, while also exposing the assumptions behind and consequences of decisions made in the process. The examples are framed taking into account societal perspectives that provide context for their regional climate statements. Although the nature of an IPCC Working Group I assessment precludes engaging with users of climate information (Section 10.5), we do cite relevant national and regional reports that give user perspectives to set a foundation from which one could distil climate information for users. We have chosen the recent Cape Town drought, Indian summer-monsoon trends and the Mediterranean summer warming because they provide a geographically diverse set of locations and relevant processes and because

ACCEPTED VERSION SUBJECT TO FINAL EDITING

most of the components for constructing regional climate information outlined in Chapter 10 are directly relevant to each case.

The three comprehensive examples follow a similar structure:

- Motivation and regional context
- The region's climate
- Observational issues
- Relevant anthropogenic and natural drivers
- Model simulation and attribution over the historical period
- Future climate information from global simulations
- Future climate information from regional downscaling
- Storylines
- Climate information distilled from multiple lines of evidence

Following this structure, construction of the regional climate information presented in these examples depends on an assessment of observational uncertainty relative to the magnitude of a climate-change signal (Section 10.2), the evaluations of model performance to judge the fitness for purpose of a given model (Section 10.3), and expert judgement. These factors contribute to attribution of historical climate-change signals (Section 10.4), recognizing that attribution must account for the interplay between externally forced signals and unforced internal variability. This interplay is explored using multiple model ensembles, including, when appropriate and feasible, single-model initial-condition large ensembles (SMILEs). The multiple lines of evidence for the climate information may conflict, thus requiring distillation of the evidence (Section 10.5) to arrive at climate-change statements. When moving from global climate information to climate information at the regional scale, following the structure above provides a basis for arriving at relevant and credible climate information. The comprehensive examples of distilling climate information thus show the value of working with multiple lines of evidence to develop robust climate change information for a region.

In addition to the three comprehensive examples, this section contains two additional examples analysing multiple sources of regional climate information. Box 10.3 on urban climate assesses information that provides a foundation for understanding climatic behaviour in urban areas and its projected change. Cross-Chapter Box 10.4 on climate change over the Hindu Kush Himalaya assembles information rooted in several chapters and previous assessment reports to assess understanding of several climate elements (temperature, precipitation, snow and glaciers, and extreme events) for the region and their projected changes.

As these examples will show, the distillation process of regional climate information from multiple lines of evidence can vary substantially from one case to another. Confidence in the distilled regional climate information is enhanced when there is agreement across multiple lines of evidence, but the outcome of distilling regional climate information can be limited by inconsistent or contradictory sources.

10.6.2 Cape Town Drought

10.6.2.1 Motivation and regional context

Cape Town's "Day Zero" water crisis in 2018 threatened a shut-down of water supply to 3.4 million inhabitants of the city and resulted in domestic water use restriction of 50 litres per person per day (pre-drought unconstrained water use was ~170 litres per person per day, DWA, 2013) lasting for nine months, punitive water tariffs, and temporary closure of irrigation systems. Problems with water supply in many large cities in developing countries are endemic and rarely reported internationally. The water crisis in Cape Town attracted considerable international attention to a city with functional government structures, well developed services (compared to other urban centres in Africa), a centre of international tourism, and an economic hub with GDP of USD22 billion (~USD 7,500 per capita, Gallie et al., 2018). Economic and social impacts of the crisis were significant. Loss of revenue for companies of all sizes resulted not only from the scaling down of water-dependent activities, but also from the need to invest in water-efficient technologies and processes.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Tourism was affected through reduced arrivals and bookings, although only temporarily (CTT, 2018). In the agricultural sector, 30,000 people were laid-off and production dropped by 20% (Piennaar and Boonzaaier, 2018). The crisis initially polarized society, with conflict emerging between various water users and erosion of trust in the government, but eventually social cohesion and an acute awareness of limited water resources emerged (Robins, 2019).

Cape Town's crisis resulted from a combination of a strong, rare multi-year meteorological drought (Figure 10.18), estimated at 1 in 300 years (Wolski, 2018), and factors related to the nature of the water supply system, operational water management and water resource policies. Cape Town was very successful in implementing water-saving actions after the previous drought of 2000–2003, reducing water losses from over 22% to 15% (Frame and Killick, 2007; DWA, 2013), breaking the previous coupling of growth in water demand with growth in population. As a consequence, Cape Town won a Water Smart City award from the C40 Cities program only three years prior to the crisis. However, the water-saving actions, together with changing priorities in water resource provision from infrastructure-oriented towards resource and demand management, may well have led to delays in implementation of the expansion of water supply infrastructure (Muller, 2018). The expansion plan, formulated a decade prior to the crisis, included an expectation of long-term climate-change drying in the region (DWAF, 2007). The crisis also exposed structural deficiencies of water management and inadequacy of a policy process in which decisions about local water resources are taken at a national level, particularly in a situation of political tension (Visser, 2018). The crisis was widely seen as a harbinger of future problems to be faced by the city, and a highlight of vulnerability of many cities in the world resulting from the interplay of three factors: 1) the fast urban-population growth, 2) the economic, policy, infrastructural and water resource paradigms and constraints, and 3) anthropogenic climate change.

[START FIGURE 10.18 HERE]

Figure 10.18: Historical and projected rainfall and Southern Annular Mode (SAM) over the Cape Town region. (a) Yearly accumulation of rainfall (in mm) obtained by summing monthly totals between January and December, with the drought years 2015 (orange), 2016 (red), and 2017 (purple) highlighted in colour. (b) Monthly rainfall for the drought years (in colour) compared with the 1981–2014 climatology (grey line). Rainfall in (a) and (b) is the average of 20 quality controlled and gap-filled series from stations within the Cape Town region (31°S–35°S, 18°W–20.5°W). (c) Time series of the SAM index and of historical and projected rainfall anomalies (%, baseline 1980–2010) over the Cape Town region. Observed data presented as 30-year running means of relative total annual rainfall over the Cape Town region for station-based data (black line, average of 20 stations as in (a) and (b)), and gridded data (average of all grid cells falling within 31°S–35°S, 18°W–20.5°W): GPCC (green line) and CRU TS (olive line). Model ensemble results presented as the 90th-percentile range of relative 30-year running means of rainfall and the SAM index from 35 CMIP5 (blue shading) and 35 CMIP6 (red shading) simulations, 6 CORDEX simulations driven by 1 to 10 GCMs (cyan shading), 6 CCAM (purple shading) simulations from individual ensemble members, and 50 members from the MIROC6 SMILE simulations (orange shading). The light blue, dark red and yellow lines correspond to NCEP/NCAR, ERA20C and 20CR, respectively. The SAM index is calculated from sea-level pressure reanalysis and GCM data as per Gong and Wang (1999) and averaged over the aforementioned bounding box. CMIP5, CORDEX and CCAM projections use RCP8.5, and CMIP6 and MIROC6 SMILE projections use SSP5-8.5. (d) Historical and projected trends in rainfall over the Cape Town region and in the SAM index. Observations and gridded data processed as in (c). Trends calculated as Theil-Sen trend with block-bootstrap confidence interval estimate. Markers show median trend, bars 95% confidence interval. GCMs in each CMIP group were ordered according to the magnitude of trend in rainfall, and the same order is maintained in panels showing trends in the SAM. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.18 HERE]

10.6.2.2 The region's climate

ACCEPTED VERSION SUBJECT TO FINAL EDITING

An evaluation of the relative role of rainfall and temperature signal in the 2015–2017 hydrological drought gives a strong indication that lack of rainfall was the primary driver (Otto et al., 2018) leading to the 2018 water crisis. Thus, the remainder of this section focuses on rainfall. Section 11.6 offers a discussion of African drought over broader areas, including mechanisms relevant to them.

Cape Town is located at the southwestern tip of Africa, within an approximately 100 km x 300 km region that receives 80% of its rainfall during the austral winter (March to October), with the largest portion in June to August. In the vicinity of Cape Town, rainfall is strongly heterogeneous, ranging from ~300 mm/year on coastal plains to >2,000 mm/year in mountain ranges. The Cape Town water supply relies on surface water reservoirs located in a few small mountain catchments (~800 km^2 in total). The Cape Town region receives 85% of its rainfall from a series of cold fronts forming within mid-latitude cyclones. The remainder is brought in by infrequent cut-off lows that occur throughout the year (Favre et al., 2013). This creates a very strong water resource dependency on a single rainfall delivery mechanism that may be strongly affected by anthropogenic climate change (Chapter 4, Section 10.6.2.6).

The 2015–2017 drought had strong low-rainfall anomalies in shoulder seasons (March to May and September to November, though weaker in the latter), and average rainfall in June and July (Sousa et al., 2018a; Mahlalela et al., 2019). The anomaly resulted from fewer rainfall events and lower average intensity of events. The anomaly was strongest in the mountainous region where the water supply system's catchments are located (Wolski et al., 2021).

Although the 2015–2017 drought was unprecedented in the historical record, the Cape Town region has experienced other droughts of substantial magnitude, notably in the 1930s, 1970s and more recently in 2000–2003. Long term (>90 years) rainfall trends are mixed in sign, location-dependent, and weak (Kruger and Nxumalo, 2017; Wolski et al., 2021); mid-term (~50 years) trends are similarly mixed in sign (MacKellar et al., 2014). In the southwestern part of the region, rainfall is mostly decreasing in the post 1981 period, particularly in December-January-February and March-April-May, although there is no trend or a weak wetting in June-July-August (Sousa et al., 2018a; Wolski et al., 2021). Rainfall trends of similar magnitude and duration to the post-1981 trend accompanied previous strong droughts in the region (Wolski et al., 2021).

10.6.2.3 Observational issues

South Africa and the Cape Town region have good instrumental weather data. Records start in the late 1800s, with in excess of 10 gauges reporting since the 1920s, expanding to ~80 gauges in the 1980s, but the number of stations has declined since. The mountains have only a few stations, which receive more than 1,000 mm/year. In view of the strong heterogeneity of rainfall, changes in the number of stations contributing to datasets such as CRU and GPCP results in a lack of consistency between them, which limits their reliability in the region (Wolski et al., 2021; Section 10.2).

10.6.2.4 Relevant anthropogenic and natural drivers

Because the primary rainfall mechanism is frontal rain, the most relevant large-scale drivers are those that affect cyclogenesis, frontogenesis and the mid-latitude westerlies' latitudinal position and moisture supply. These drivers and, thus, the region's rainfall are linked to the Antarctic Oscillation (AAO; Reason and Rouault, 2005) or Southern Annual Mode (SAM), the dominant monthly and interannual mode of Southern Hemisphere atmospheric variability, and a measure of the pressure gradient between mid- and high-latitudes. (see Sections 3.3, 3.7, 4.3 and Annex IV.2.2 for more general discussion of the SAM.) While in the post-1930 period, the SAM displays a long-term positive trend, the Cape Town region's rainfall does not, and only the post-1979 trends of rainfall and SAM are conceptually consistent, i.e., a positive trend in the SAM is associated with a negative trend in rainfall (Section 10.6.2.5 and Figure 10.18). There is also good agreement between the seasonality of the SAM and rainfall trends in the post-1979 period: a drying trend appears strongly in December to February and March to May, but not in June to August and September to November (Wolski et al., 2021), and trends in the SAM have similar seasonal dependence (Lim et al., 2016b; Section 3.7.2).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Additionally, there is a similar seasonal pattern in the post-1979 trends in indices capturing the southern edge of the Hadley circulation (Grise et al., 2018).

In the longer-term, Cape Town regional rainfall is characterized by a multi-decadal scale quasi-periodicity (Figure 10.18; Dieppois et al., 2019; Wolski et al., 2021), with the 2015–2017 drought and previous strong droughts (1930s and 1970s) occurring during the rainfall's periodic low phases. However, the studies linking the Cape Town 2015–2017 drought to the hemispheric processes expressed by the SAM (Sousa et al., 2018a; Burls et al., 2019; Mahlalela et al., 2019) focused almost exclusively on the post-1979 period, when global reanalyses are available. Detailed understanding of the drivers of previous (1930s and 1970s) Cape Town region droughts and the role of hemispheric processes expressed by the SAM in the pre-1979 period is missing.

The Cape Town regional rainfall is also potentially linked to other hemispheric phenomena, such as the expansion of the tropics and, specifically, the South Atlantic high-pressure system and the position of the subtropical jet, which share some variability with the SAM. The relationships between these phenomena and Cape Town rainfall have not been thoroughly investigated outside of the context of the 2015–2017 drought, but the drought itself was associated with poleward expansion of the subtropical anticyclones in the South Atlantic and South Indian Oceans and (a resulting) poleward displacement of the moisture corridor across the South Atlantic (Sousa et al., 2018a), as well as a weaker subtropical jet (Mahlalela et al., 2019). Burls et al. (2019) also link the decline in the number of rainy days to the increase in sea-level pressure along the poleward flank of the South Atlantic high-pressure system and the intensity of the post-frontal ridging high. Additionally, there is a possible linkage between Cape Town rainfall and near-shore cold sea surface temperature (SST) anomalies arising from Ekman upwelling due to reduced westerly and increased south-easterly winds. These might lead to suppression of convection and reduction of rainfall over land (Rouault et al., 2010). All these phenomena are conceptually consistent with the poleward migration of the westerlies and expansion of the tropics.

Rainfall in the Cape Town region also responds to SST anomalies in the Southeast Atlantic, including the Agulhas Current retroflection region, which may drive intensification of low-pressure systems, leading to the trailing front strengthening as it makes landfall over the Cape Town region (Reason and Jagadheesha, 2005). There are also linkages at seasonal time scale between the Cape Town regional rainfall and Antarctic sea ice (Blamey and Reason, 2007).

In addition to mid-latitude controls, subtropical processes also play a role in the Cape Town region's rainfall variability. The 10˚–30˚S region of the subtropical Atlantic, parts of the South American continent and even parts of the African continent north of Cape Town are sources of moisture for atmospheric river events contributing to frontal rainfall (Blamey et al., 2018; Ramos et al., 2019), with implications for the 2015–2017 drought (Sousa et al., 2018a). Also, the second major rainfall contributing system, cut-off-lows, is conditional on moisture supply from the sub-tropics (Abba Omar and Abiodun, 2020).

Although El Niño-Southern Oscillation (ENSO) influences climate in southern Africa, any relationship between ENSO and Cape Town's rainfall is weak and inconsistent, showing the strongest impact in May to June (Philippon et al., 2012). ENSO, however, does influence large-scale processes and phenomena relevant to the drought, though the relationship between ENSO and the SAM is complex, with each ENSO event influencing the SAM differently in different seasons (Ding et al., 2012). Similarly, ENSO affects meridional circulation and thus the subtropical anticyclone as well as the polar and subtropical jets (Seager et al., 2019), but only modifying, not controlling, their role in Cape Town's rainfall.

Paleoclimate studies reveal that long-term variability in the winter rainfall region of South Africa (including Cape Town) is consistent with a general framework of warming/cooling-induced latitudinal migration of the westerlies and transformation of the subtropical high-pressure belt and associated hemispherical processes (see section 10.2.3.2 for assessment of paleoclimate analysis). The synchronicity of winter rainfall with Antarctic ice-core-derived polar temperature anomalies is consistently revealed in studies using different paleoclimate proxies and time scales of 1.4k (Stager et al., 2012), ~3k (Hahn et al., 2016) and 12k years (Weldeab et al., 2013). Changes in rainfall regimes at shorter (decadal) time scales appear to reflect influence of local processes such as the Agulhas current's interaction with the Atlantic, resulting in changes

ACCEPTED VERSION SUBJECT TO FINAL EDITING

in SST and coastal upwelling, as well as modification of the wind tracks by topography (Stager et al., 2012).

10.6.2.5 Model simulation and attribution over the historical period

Due to the small scale of the Cape Town region, robust comparison of CMIP simulations to observations is difficult. However, in general, CMIP5 models capture well the seasonality, such as the dominance of austral winter rains, although they overestimate the peak and underestimate the shoulder season rainfall (Mahlalela et al., 2019). Trends in rainfall are particularly difficult to assess as they are generally weak and depend strongly on the time period and dataset adopted for the analyses (Section 10.6.2.3). A multi-method attribution study (Otto et al., 2018) estimates the probability of the 2015–2017 drought to have increased by a factor of 3 since pre-industrial times (with a wide 95% confidence interval of 1.5 to 6). However, throughout the 20th century, a substantial portion of the global climate models (GCMs; ~36% of CMIP5 and 44% of CMIP6 models, as well as many of the MIROC SMILE members) simulate a statistically significant (95% level) decline in total annual rainfall, while there is no robust long-term trend in observations (Figure 10.18). Section 10.4 offers a more detailed assessment of attribution challenges.

GCMs capture the overall behaviour of the observed main hemispherical processes, such as the expansion of the tropics, a positive trend in SAM and the poleward shift of the westerly jet. However, they fail to capture details of their observed climatology and variability (Simpson and Polvani, 2016), and the magnitudes of simulated trends vary, though the models typically underestimate observed trends in these processes (Purich et al., 2013; Staten et al., 2018). In general, CMIP5 models do capture the SAM-regional rainfall association, although not consistently across all seasons (Purich et al., 2013; Lim et al., 2016a).

10.6.2.6 Future climate information from global simulations

GCMs show strong consistency in a drying signal for the Cape Town region, with the reduction in total annual rainfall ranging up to 20% by the end of the 21st century in CMIP5 RCP8.5 and CMIP6 SSP5-8.5 simulations (Almazroui et al., 2020a; Figure 10.18). The consistency across the models is a robust signal compared to the rest of southern Africa, where the climate change signal varies spatially: stronger drying in the west and moderate drying or weak wetting in the east (DEA, 2013, 2018; Atlas.4.4 for further discussion of southern Africa precipitation projections). Rainfall changes projected for the Cape Town region are consistent with projected changes in hemispheric-scale processes and regional-scale dynamics that point toward reduced frequency of frontal systems affecting that region. These changes include robust signals in CMIP5 models for the Southern Hemisphere for a poleward expansion of the tropics (Hu et al., 2013b), poleward displacement of mid-latitude storm tracks (Chang et al., 2012), increased strength and poleward shift of the westerly winds (Bracegirdle et al., 2018) and subtropical jet-streams (Chenoli et al., 2017), and a shift toward a more positive phase of the SAM (Lim et al., 2016a). However, despite the consistency in circulation changes, the emergence of anthropogenic rainfall change above unforced variability in southwestern Africa remains uncertain for annual rainfall throughout most of the 21st century, even under SSP5-8.5 (Section 10.4, Figure 10.15).

There is also a substantial increase in the frequency of conditions supporting atmospheric rivers and water vapour transport towards the southwest coast of southern Africa in the projected climate (Espinoza et al., 2018). This behaviour has strong implications for the region, as most topographically high locations receive rainfall from persistent atmospheric rivers (Blamey et al., 2018). A thorough understanding of the role of atmospheric rivers in the Cape Town region under a changing climate is missing.

10.6.2.7 Future climate information from regional downscaling

Dynamical downscaling studies implemented with a stretched-grid model (Engelbrecht et al., 2009) revealed a signal compatible with the driving CMIP5 ensemble, that is, consistent drying throughout the region, amplifying in time, irrespective of the considered emission scenario and the generation of GCMs (DEA,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2013, 2018). A multi-model CORDEX ensemble indicates a robust signal of reduction of total annual rainfall in the future, although there is less agreement on how changes in rainfall occurrence may evolve in the region, such as through fewer consecutive rain days or longer dry spells (Abiodun et al., 2017; Maúre et al., 2018). For the end of the century under RCP8.5, Dosio et al. (2019) also found drying. Moreover, in their analysis, the drying is associated with an increase in the number of consecutive dry days and a reduction in number of rainy days. Their results are consistent with the driving GCMs for all the precipitation indices, and they are robust independent of the choice of the regional climate model (RCM) or GCM. However, collectively, these analyses indicate that uncertainty remains in the characteristics of the precipitation decrease.

10.6.2.8 Storyline approaches

There is a consistency in rainfall projections with the projections of rainfall drivers and with the general understanding of the influence of global warming on the circulation dynamics and rainfall patterns in the region. Thus, the expansion of the South Atlantic high-pressure system, related to widespread warming of the tropics and poleward shift of the subsiding limb of the Hadley cell, is associated with the southward displacement of the subtropical jet, and southward migration of mid-latitude westerlies and storm tracks, in addition to changes in the SAM (Section 10.6.2.4). These effects are also relatively consistent with recent (post-1980s) declines in rainfall in the Cape Town region. The storyline of an extended drought is thus a set of events that can yield reduced rainfall in the Cape Town region: poleward shift of the downward branch of the Hadley cell that produces a sustained southward shift in mid-latitude westerlies and storm tracks. The behaviour is potentially reinforced by changes in the SAM.

10.6.2.9 Climate information distilled from multiple lines of evidence

There is *high agreement* among observational data and reanalyses that the recent (post-1979) downward trend in the Cape Town region's rainfall leading to the 2015–2017 drought is related to the hemispheric processes of poleward shift in the westerlies and expansion of the Hadley circulation. However, there is less support for the precipitation-circulation relationship in historical CMIP5 and CMIP6 simulations. As a consequence, there is only *medium confidence* that these process changes produced the 2015–2017 drought leading to the 2018 water crisis.

For the water-resource planner who has to deal with potential drought like the 2015-2017 event, several lines of evidence indicate future drying: the projected precipitation by GCMs and RCMs of different spatial resolutions, and the observed and projected changes of circulation patterns consistent with drier conditions, the paleoclimatic evidence confirming a millennial-scale circulation-rainfall link. However, the distillation is limited by a lack of information about whether or not a relationship between Cape Town precipitation and large-scale circulation processes adequately explains droughts in the twentieth century prior to 1979.

Thus, although a clear association appears in observations from 1979 onward between increasing GHG concentrations, drying in the Cape Town region and behaviour of a key circulation process, the SAM, further analysis suggests caution. Not all GCMs show the historical post-1979 association among these factors, and when the observational record is extended back further to times when the anthropogenic greenhouse forcing was weaker, there is no strong association between the SAM and Cape Town drought. Thus, there is only *medium confidence* in the expectation of a future drier climate for Cape Town.

10.6.3 Indian Summer Monsoon

10.6.3.1 Motivation and regional context

The Indian summer monsoon provides 80% of the country's annual rainfall from June to September, supplying the majority of water for agriculture, industry, drinking and sanitation to over a billion people.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Any variations in the monsoon on time scales from days to decades can have large impacts (Challinor et al., 2006; Gadgil and Gadgil, 2006). Evidence from paleoclimate records (Sections 8.3.2.4.1) shows *high confidence* in a weakened Indian monsoon during cold epochs of the past such as the Younger Dryas (12,800-11,600 years ago) as measured by speleothem oxygen isotopes (Kathayat et al., 2016). There is a pressing need to understand if the monsoon will change in the future under anthropogenic forcing and to quantify such changes. Multiple datasets have shown robust negative trends since the 1950s until the turn of the century (Bollasina et al., 2011) followed by a recovery (Jin and Wang, 2017), yet repeated assessments project the monsoon to increase in strength under enhanced GHG forcing (Christensen et al., 2007, 2013; Sections 8.3.2.4.1 and 8.4.2.4.1). The apparent contradiction between future projections and observed historical trends makes the region an ideal choice for an in-depth assessment. The reader is also referred to the South Asia (SAS) regional assessment of precipitation extremes (Section 11.9), which is not discussed here for brevity.

10.6.3.2 The regional climate of India

Local geography gives rise to distinct differences in societal experience of the summer monsoon. The southwesterly monsoon winds are incident upon the Western Ghats mountains on the west coast, leading to orographic enhancement and heavy rains (Shige et al., 2017), which supply rivers with water for much of the southern peninsula, often the subject of inter-regional water disputes. The northern plains contain the Ganges river and also India's most intensive agriculture, both rainfed and irrigated. Synoptic systems known as monsoon depressions cross the northern east coast, supplying much of the rain in central India (Hunt and Fletcher, 2019). Further north, the eastern Himalayas are dominated by the summer monsoon, while the western Himalayas receive most rainfall from western disturbances during winter (Palazzi et al., 2013). Meanwhile, southeastern India sits under a rain shadow (the only region to receive more rainfall during the winter monsoon).

10.6.3.3 Observational issues for India

India has one of the oldest rain-gauge networks in the world, leading to the production of numerous observational products (reviewed in Khouider et al., 2020). Gridded gauge-based products dating back to the 19th century reveal pronounced decadal variability (Sontakke et al., 2008). Trends for India over the whole 20th century are inconclusive (Knutson and Zeng, 2018), although declining over central and northern areas (Roxy et al., 2015). Assessment of multiple observational datasets covering the Indian summer monsoon reveals significant declining rainfall over the second half of the 20th century (Section 8.3.2.4.1, Figure 10.19c,d). A subsequent recovery has been noted since the early 2000s (Jin and Wang, 2017).

Observational products containing critical inhomogeneities in gauge distribution and reporting over time are acknowledged as suitable for mesoscale analysis (Rajeevan and Bhate, 2009), while use for climate trends requires consistent reporting over time from quality-controlled gauges (e.g., ~2000 gauges since the 1950s in Rajeevan et al., 2006). A newer 0.25°-gridded product covering 1901 onwards (Pai et al., 2014, 2015), based on Shepard's interpolation method for irregularly-spaced stations (Shepard, 1968), shows increased intensity of daily rainfall and extremes over some regions, especially in the late-20th century. However, changes to the inputted gauges may have introduced an artificial jump in extreme rainfall since 1975 over central India (Section 10.2.2.3; Lin and Huybers, 2019). They suggest that this method may have masked declines in mean rainfall and highlight the need for availability of raw gauge data to allow transparent assessments. Khouider et al. (2020) have successfully tested a probabilistic interpolation method for India to overcome problems inherent in algorithms based on inverse-distance weighting when applied to data-sparse regions. An example snapshot of the uneven distribution of rain gauges in a common observational product is shown in Figure 10.19a.

The uncertainty among local and international observational products for India can pose challenges when evaluating climate models (as in Section 10.2.2.6; Prakash et al., 2015). For the seasonal mean summer monsoon rainfall, Collins et al. (2013) found large biases separating many CMIP5 models from the available

ACCEPTED VERSION SUBJECT TO FINAL EDITING

observational products. However, for seasonal mean variability, the spread across observational products was larger than across the CMIP5 ensemble.

10.6.3.4 Relevant anthropogenic and natural drivers for long-term change

The relevant drivers for long-term change in the mean Indian summer monsoon are summarised briefly:

- Increased greenhouse gas (GHG) concentrations (chiefly CO_2) are a strong contributor to changes in the monsoon, with repercussions for the meridional temperature contrast driving the monsoon circulation (Ueda et al., 2006; Roxy et al., 2015), for the monsoon winds in the lower troposphere (Cherchi et al., 2011; Krishnan et al., 2013), or for the availability of moisture from the Indian Ocean (May, 2011).
- Industrial emissions of sulphate aerosol predominantly in the Northern Hemisphere could change inter-hemispheric energy transports and weaken the monsoon (Polson et al., 2014; Undorf et al., 2018). The effect of local anthropogenic emissions of black carbon (chiefly from cooking fires) is uncertain (Lau and Kim, 2006; Nigam and Bollasina, 2010).
- India's green revolution over the late-20th century led to considerable land-use change, with massive expansion of agriculture at the expense of forest and shrublands. As a result, India's northern plains feature widespread irrigation, suggested to be a cause of drying (Mathur and AchutaRao, 2020).
- Decadal modes of variability such as the Pacific Decadal Variability (PDV, Annex IV) and Atlantic Multidecadal Variability (AMV, Annex IV), which may be partly forced (Section 3.7.7), are known to cause decadal modulation of the monsoon (Krishnamurthy and Krishnamurthy, 2014; Naidu et al., 2020).

The interplay of these external and internal drivers is key to understanding past and future monsoon change.

10.6.3.5 Model simulation and attribution of drying over the historical period

The robust decline of Indian summer monsoon rainfall averaged over India in the second half of the 20th century (Section 10.6.3.3) is not in line with expectations arising from thermodynamic constraints on the water cycle in a warming world (Section 8.2.2) and has been regarded as a puzzle (Goswami et al., 2006). Assessing the attribution of 20th-century changes to Indian rainfall is the subject of coordinated modelling under the Global Monsoon MIP (GMMIP; Zhou et al., 2016), but is complicated by long-standing dry biases in coupled CMIP3, CMIP5 (Sperber et al., 2013) and CMIP6 (Figure 10.19b) GCMs. These dry biases are connected to a lower tropospheric circulation that is too weak (Sperber et al., 2013) and wet biases in the equatorial Indian Ocean (Bollasina and Ming, 2013). Section 8.3.2.4.1 finds *high confidence* that anthropogenic aerosol emissions have dominated the observed declining trends of countrywide Indian summer monsoon rainfall, consistent with findings at the global-monsoon scale (Section 3.3.3.2).

Stronger Northern Hemisphere aerosol emissions cool it relative to the Southern Hemisphere, increasing northward energy transport at the expense of moisture transport towards India (Bollasina et al., 2011). The attribution to anthropogenic aerosols is supported in CMIP5 single-forcing experiments, including some testing the sensitivity to local and remote emissions (Guo et al., 2015, 2016; Shawki et al., 2018), comparing CMIP5 GCMs forced by both aerosol and GHG to GHG only (Salzmann et al., 2014) and reducing emissions to pre-industrial levels (Takahashi et al., 2018). The large spread between individual model realisations of comparable magnitude to the aerosol-induced signal suggested to Salzmann et al. (2014) that internal variability may also play a role over regions such as northern-central India. Further uncertainty surrounds the level of radiative forcing. Dittus et al. (2020) forced a GCM with historical aerosol emissions scaled between 0.2 and 1.5 times their observed values, representing the spread in CMIP5 effective radiative forcing. The strongest forcing led to around 0.5 mm day^{-1} less late-20th century Indian monsoon rainfall than the weakest (Shonk et al., 2020). Meanwhile, the uncertainty surrounding aerosol-cloud interactions could change the sign of long-term precipitation trends (Takahashi et al., 2018).

There is some evidence that declining Indian monsoon rainfall is due to regional SST warming patterns, themselves arising due to radiative forcing from GHG (e.g., in the Indian Ocean, Guemas et al., 2013). Roxy

ACCEPTED VERSION SUBJECT TO FINAL EDITING

et al. (2015) artificially raised SST in a coupled GCM in the equatorial Indian Ocean (the region of strongest observed SST warming), leading to a weakened monsoon. Annamalai et al. (2013) used a GCM to suggest instead that preferential warming of the western North Pacific may force a Rossby-wave response to its west that weakens the monsoon through dry advection and subsidence. These hypotheses are not borne out in GHG-forced future projections (Section 10.6.3.6).

A small anthropogenic contribution may be expected from local land-use/land-cover changes and land management. India is the world's most irrigated region with around 0.5 mm/day in places, although peaking higher in summer (Cook et al., 2015b; McDermid et al., 2017). Including irrigation in GCMs and RCMs slows the monsoon circulation and diminishes rainfall (Lucas-Picher et al., 2011; Guimberteau et al., 2012; Shukla et al., 2014; Tuinenburg et al., 2014; Cook et al., 2015b) due to reduced surface temperature (Thiery et al., 2017), reducing the monsoon wind and moisture fluxes towards India (Mathur and AchutaRao, 2020). However, implementation methodologies for irrigation in climate models are simplified and often do not account for spatial heterogeneity while overestimating demand and supply (Nazemi and Wheater, 2015; Pokhrel et al., 2016; Section 10.3.3.6). Changing forest cover to agricultural land in an RCM (Paul et al, 2016) finds weakened summer monsoon rainfall especially in central and eastern India, due to decreased local evapotranspiration. Decreased evapotranspiration from a warmer surface since the 1950s in the CMIP5 ensemble may also feedback on the supply of moisture (Ramarao et al., 2015). Based on a global atmospheric GCM study and literature review, Krishnan et al. (2016) support the role of land-use/land-cover change in adding to the effects of aerosol in weakening the monsoon, in addition to dynamic effects on the circulation caused by rapid warming of the Indian Ocean.

In addition to anthropogenic forcing, there is evidence that internal variability in the Pacific is a significant driver. Huang et al. (2020b) compared a large perturbed-physics ensemble (HadCM3C) with a SMILE for the historical period. Ensemble members replicating the negative Indian rainfall trend were accompanied by a strong phase change in the PDV from negative to positive, consistent with SST observations. Jin and Wang (2017) have demonstrated increasing Indian monsoon rainfall since 2002 in a variety of observed datasets, suggesting the increase is due either to a change in dominance of a particular forcing (for example from aerosol to GHG) or to a change in phase of internal variability such as the PDV. Huang et al. (2020b) partially attribute the rainfall recovery to a phase change in the PDV, supported by a SMILE study combined with reanalyses (Ha et al., 2020).

The drying trend of Indian summer monsoon rainfall since the mid-20th century can be attributed with *high confidence* to aerosol as the dominant anthropogenic forcing with a further contribution from internal variability, supported by the review of Wang et al. (2020) including CMIP6 results. Understanding the interplay between anthropogenic and internal drivers will be important for understanding future change.

10.6.3.6 Future climate projections from global simulations

The AR5 (Christensen et al., 2013) concluded that Indian summer monsoon rainfall will strengthen under all RCP future climate scenarios, while the circulation will weaken (*medium confidence*). SR1.5 (Hoegh-Guldberg et al., 2018) found only *low confidence* in projections of monsoon change at 1.5°C and 2°C, or any difference between them. The AR6 assessment of Chapter 8 (8.4.2.4.1) finds more precipitation in future projections (also depicted in Figure 10.19c,d,e), supported by reviews of CMIP3, CMIP5 and CMIP6 models (Turner and Annamalai, 2012; Kitoh, 2017; Chen et al., 2020b; Wang et al., 2020).

Given the assessment for a future wetter monsoon dominated by GHG emissions and attribution of the late-20th century decline to aerosol (Sections 8.3.2.4.1 and 10.6.3.5), the change between dominant forcings will lead, at some point, to a positive trend. For example, RCP4.5 experiments in an atmospheric GCM forced by coupled model-derived future SSTs showed continuation of 20th-century drying, before a rainfall recovery (Krishnan et al., 2016). By holding aerosol emissions at 2005 levels, lower monsoon rainfall is found throughout the 21st century than in a standard RCP8.5 scenario (Zhao et al., 2019), suggesting that the timing of the recovery will be partially controlled by the rate at which aerosol emissions decline. The spread in spatial distribution of aerosol emissions in SSPs may also play a role in near-term projections (Samset et al.,

ACCEPTED VERSION SUBJECT TO FINAL EDITING

2019). Under divergent air-quality policies, SSP3 features a dipole of declining sulphate emissions for China but increases over India, leading to suppression of GHG-related precipitation increases there (Wilcox et al., 2020). For the near-term future around the mid-21st century, the interplay between internal variability and external forcing must be considered (Singh and AchutaRao, 2018). Huang et al. (2020a) used two SMILEs to show that internal variability related to PDV could potentially overcome the GHG-forced upward trend in Indian monsoon rainfall, consistent with assessments of the global monsoon for the near term (Section 4.4.1.4). Emergence of the anthropogenic signal for South Asian precipitation is shown from the 2050s onwards in CMIP6 (Figure 10.15b).

In long-term projections, robust signals consist of a weakened upper-tropospheric meridional temperature gradient, either due to upper-level heating over the tropical Pacific (Sooraj et al., 2015) or Indian Oceans (Sabeerali and Ajayamohan, 2018) in CMIP5, and increased seasonal mean rainfall, including in CMIP6 (Almazroui et al., 2020c; Wang et al., 2020). The weakened temperature gradient combines with increased atmospheric stability to weaken the monsoon overturning circulation, with some findings showing northward movement of the lower-tropospheric monsoon winds in response to a stronger land-sea temperature contrast in CMIP3 and CMIP5 (Sandeep and Ajayamohan, 2015; Endo et al., 2018). The northward shift was also found in the genesis of synoptic systems (monsoon depressions) in a single high-resolution atmospheric GCM forced by an ensemble of SSTs derived from four GCMs under the RCP8.5 scenario (Sandeep et al., 2018).

Projections can also be expressed in terms of global-mean warming levels (GWLs) rather than time horizons (Cross-Chapter Box 11.1). Advancing upon SR1.5, amplification of mean and extreme monsoon rainfall at 2.0°C compared to 1.5°C has been found both by an atmospheric GCM forced by future SST patterns (Chevuturi et al., 2018) and using time slices in CMIP5 GCMs (Yaduvanshi et al., 2019; Zhang et al., 2020a). These findings are consistent with the general scaling of Indian monsoon precipitation per degree of warming in CMIP5 (Zhang et al., 2019) and CMIP6 (Wang et al., 2020). Increasing GWLs also lead to emergence of the anthropogenic signal over larger proportions of the South Asian region (Figure 10.15a).

Decomposition of the increased rainfall signal showed that while the dynamic component led to a drying tendency, this was overcome by the thermodynamic contribution (Sooraj et al., 2015; Chen et al., 2020b). Alternative decomposition experiments using atmospheric GCMs and their coupled counterparts found increases in the lower-tropospheric temperature gradient and monsoon rainfall to be dominated by the fast radiative response to GHG increase rather than SST changes (Li and Ting, 2017; Endo et al., 2018). The response to SST forcing featured a large model spread, particularly arising from the dynamic component (Li and Ting, 2017). Chen and Zhou (2015) found that the Indo-Pacific SST warming pattern dominated the uncertainty in Indian monsoon rainfall change. Finally, in assessing the relative impact of CO_2 radiative forcing and plant physiological changes in quadrupled CO_2 experiments in four Earth system models, Cui et al. (2020) showed little impact of plant physiology on annual rainfall for the Indian region.

While several of the above studies selected model subsets to constrain future projections based on standard performance metrics of the historical period, such as pattern correlation and root-mean-square error, Latif et al. (2018) included a performance measure based on agreement with historical rainfall trends. This is an unproven constraint for regional projections (Section 10.3.3.9), since the 20th-century rainfall trend over India is assessed to have been driven chiefly by aerosol and other factors such as PDV (Sections 8.3.2.4.1 and 10.6.3.5), while the dominant late-21st century forcing is GHG emissions. Modern emergent-constraint techniques (Section 10.3.4.2) are being applied to the Indian monsoon such as Li et al. (2017), who found that models with excessive tropical western Pacific rainfall tend to project a greater Indian monsoon rainfall change in future, due to an exaggerated cloud-radiation feedback. Correcting for this bias reduces the future change.

[START FIGURE 10.19 HERE]

Figure 10.19: Changes in the Indian summer monsoon in the historical and future periods. (a) Observational uncertainty demonstrated by a snapshot of rain-gauge density (% of 0.05°-subgrid boxes containing at

ACCEPTED VERSION SUBJECT TO FINAL EDITING

least one gauge) in the APHRO-MA 0.5° daily precipitation dataset for June to September 1956. (b) Multi-model ensemble (MME)-mean bias of 34 CMIP6 models for June to September precipitation (mm day^{-1}) compared to CRU TS observations for the 1985–2010 period. (c) Maps of rainfall trends (mm day^{-1} per decade) in CRU TS observations (1950–2000), the CMIP6 MME-mean of SSP5-8.5 future projections for 2015–2100 (34 models), the CMIP6 hist-GHG and hist-aer runs, both measured over 1950 to 2000. (d) Low-pass filtered time series of June to September precipitation anomalies (%, relative to 1995–2014 baseline) averaged over the central India box shown in panel (b). The averaging region (20°N–28°N, 76°E–87°E) follows other works (Bollasina et al., 2011; Jin and Wang, 2017; Huang et al., 2020b). Time series are shown for CRU TS (brown), GPCC (dark blue), REGEN (green), APHRO-MA (light brown) observational estimates and the IITM all-India rainfall product (light blue) in comparison with the CMIP6 mean of 13 models for the all-forcings historical (pink), the aerosol-only (hist-aer, grey) and greenhouse gas-only (hist-GHG, blue). Dark red and blue lines show low-pass filtered MME-mean change in the CMIP6 historical/SSP5-8.5 (34 models) and CMIP5 historical/RCP8.5 (41 models) experiments for future projections to 2100. The filter is the same as that used in Figure 10.11(d). To the right, box-and-whisker plots show the 2081–2100 change averaged over the CMIP5 (blue) and CMIP6 (dark red) ensembles. Note that some models exceed the plotting range (CMIP5: GISS-E2-R-CC, GISS-E2-R & IPSL-CM5B-LRl and CMIP6: CanESM5-CanOE, CanESM5 & GISS-E2-1-G). (e) Precipitation linear trend (% per decade) over central India for historical 1950–2000 (left) and future 2015–2100 (right) periods in Indian monsoon rainfall in observed estimates (black crosses), the CMIP5 historical-RCP8.5 simulations (blue), the CMIP6 ensemble (dark red) for historical all-forcings experiment and SSP5-8.5 future projection, the CMIP6 hist-GHG (light blue triangles), hist-aer (grey triangles) and historical all-forcings (same sample as for hist-aer and hist-GHG, pink circles). Ensemble means are also shown. Box-and-whisker plots show the trend distribution of the three coupled and the d4PDF atmosphere-only (for past period only) SMILEs used throughout Chapter 10 and follow the methodology used in Figure 10.6. (f) Example spread of trends (mm day^{-1} per decade) out to the near term (2016–2045) in RCP8.5 SMILE experiments of the MPI-ESM model, showing the difference between the three driest and three wettest trends among ensemble members over central India. All trends are estimated using ordinary least-squares regression. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END FIGURE 10.19 HERE]

In summary, long-term future scenarios dominated by GHG increases (such as the RCPs) suggest increases in Indian summer monsoon rainfall (*high confidence*), dominated by thermodynamic mechanisms leading to increases in the available moisture. In the near-term, there is *high confidence* (*medium agreement*, *robust evidence*) that increased rainfall trends due to GHGs could be overcome by aerosol forcing or internal variability.

10.6.3.7 Future climate projections from regional downscaling

Coordinated monsoon-relevant dynamical downscaling efforts such as CORDEX South Asia (Gutowski et al., 2016; Choudhary et al., 2018) are relevant to the Indian summer monsoon, first with assessment of their added value (Sections 10.3.3.2 and Atlas.5.3.3). Singh et al. (2017) compared nine CORDEX-South Asia RCMs against their driving CMIP5 GCMs, for present-day rainfall patterns and processes related to intraseasonal variability. They found no consistent improvement other than for spatial patterns (e.g., rainfall close to better-resolved orography); some characteristics were made worse. Both the rainfall pattern and its bias were worsened in CORDEX compared to CMIP5 in Mishra et al. (2018). In contrast, Varikoden et al. (2018) found improved representation of historical rainfall patterns, such as over the Western Ghats mountains (consistent with Singh et al., 2017), reducing the dry bias; improvements were not found over the northern plains, which are dominated by synoptic variability known as monsoon depressions. Similarly, Sabin et al. (2013) compared a uniform 1°-resolution model ensemble with another zoomed to ~35 km over South Asia. Local zooming improved simulation of orographic precipitation and the monsoon trough. For the future, a surrogate approach (like pseudo-global warming, see Section 10.3.2.2) was used in an RCM to test the impacts of warming or moistening on monsoon depressions (Sørland and Sorteberg, 2016; Sørland et al., 2016). The depressions are found to give more rainfall in future, dominated by strengthened synoptic circulation from the warming perturbation. By forcing an RCM with a perturbed parameter ensemble of a

ACCEPTED VERSION SUBJECT TO FINAL EDITING

GCM, Bal et al. (2016) made projections under SRES A1B for the 2020s, 2050s and 2080s. They noted increases in rainfall of 15–24% for India. Finally, evidence from a single CORDEX South Asia RCM showed a mixed signal for changes in peak season rainfall under RCP2.6 and RCP8.5 (Ashfaq et al., 2020).

Statistical downscaling and other post-processing require calibration in historical conditions (e.g., Akhter et al., 2019) and assessment of fitness for purpose (Section 10.3.3.9) before use for future projections. Given the noted biases in GCM monsoon simulation (Section 10.6.3.5), Vigaud et al. (2013) used a variant of quantile mapping to bias adjust (Section 10.3.1.3.2 and Cross-Chapter Box 10.2) GCM outputs. For the historical period, the pattern, mean and seasonal cycle of rainfall versus the input GCMs were improved. Increased future monsoon rain, albeit in older SRES A2 projections, was found for southern India. Salvi et al. (2013) used regression-based perfect prognosis (Section 10.3.1.3.1) for the whole country at 0.5°-resolution based on five ensemble members of a GCM in SRES scenarios. They noted increases over rainy regions of west coast and northeast India, but decreases in the north, west and southeast. Madhusoodhanan et al. (2018) statistically downscaled 20 CMIP5 models to 0.05°-resolution. While the GCMs projected increased rainfall, the downscaled ensemble depicted both increasing and decreasing trends, indicating uncertainty. However, key physical processes operating at below-GCM scale cannot be resolved nor calibrated for, such as aspects of the flow around topography. This is notably an issue given the resolution disparity between the driving GCMs and output, and the regional challenges in observational data used for calibration (Section 10.6.3.3).

There are mixed messages as to whether downscaling adds value to climate projections of the Indian summer monsoon; however, there is *high confidence* in projections of precipitation changes in orographic regions given the consistent improved representation in these regions among several dynamical downscaling studies.

10.6.3.8 Storyline approaches for India

Formal storyline approaches (see Box 10.2) have been used infrequently for the Indian summer monsoon, representing a knowledge gap. In an expert-elicitation approach (Dessai et al., 2018), physically plausible futures substantiated by climate processes were constructed, focusing on a river basin in southern India. Possible outcomes were framed based on changes in two drivers: availability of moisture from the Arabian Sea and strength of the low-level flow. The narratives identified were able to explain 70% of the variance in monsoon rainfall over 1979–2013, the implication being that climate uncertainties could be easily communicated to stakeholders in the context of present-day variability.

The storylines terminology could be used to loosely describe the interplay between internal variability and forced change (see Section 10.6.3.6), such as considering the difference between groups of wettest and driest ensemble members of a SMILE for the near-term future in Figure 10.19f. However, given the interest in low-likelihood high-impact scenarios (Sutton, 2018), we can also consider possible storylines for the Indian monsoon constructed from evidence in paleoclimate records and modelling. For example, a future AMOC collapse could cause reduced monsoon rainfall (Section 8.6.1; Liu et al., 2017), offsetting increases expected due to GHG. Large tropical volcanic eruptions are also known to weaken the Asian summer monsoon, in observations and model simulations over the last millennium (Section 8.5.2.3; Zambri et al., 2017), although a hemispheric dependence is found, with southern hemisphere eruptions even strengthening the monsoon around India (Zuo et al., 2019). Typically, future climate projections do not consider plausible eruption scenarios and their mitigating effects on greenhouse warming (see also Cross-Chapter Box 4.1). A single-model ensemble (Bethke et al., 2017) demonstrates a future drier Indian monsoon relative to conditions in which volcanic eruptions are not considered, although the effects of GHG warming dominate beyond the mid-term.

The few studies on low-likelihood high-impact scenarios, often in single models, together with findings in SR1.5 (Hoegh-Guldberg et al. 2018), noting the small radiative forcing in 1.5°C or 2°C scenarios, or the absence of large aerosol emissions at the end of the 21st century in RCPs, give us *low confidence* in abrupt changes to the monsoon on this time scale.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.6.3.9 Regional climate information distilled from multiple lines of evidence

Above, we presented assessments from observational and model attribution studies of the historical period, followed by future climate projections in global and regional models, and storylines approaches including low-likelihood high impact events. Miscellaneous lines of evidence are considered here.

Our assessment could also be informed by attempting to constrain future projections of the Indian summer monsoon using paleoclimate evidence. In modelling work of the mid-Holocene (D'Agostino et al., 2019), the increased obliquity (axial tilt) and altered orbital precession lead to an enhanced monsoon with a stronger dynamic component (strengthening the mean monsoon overturning) controlling the increase in monsoon rainfall. In future climates however, the dynamic contribution decreases (Section 10.6.3.6), yet the increased thermodynamic component (greater moisture availability) overcomes this to cause a wetter monsoon. Monsoon changes under different epochs may not be governed by the same mechanisms (D'Agostino et al., 2019; Hill, 2019), making the mid-Holocene, in particular, unsuitable as a period to compare with.

Finally, the recent national climate-change assessment for India (Krishnan et al., 2020) has distilled multiple lines of evidence to show declining summer monsoon rainfall over the second half of the 20th century, attributable to emissions of anthropogenic aerosols, while future projections informed by CMIP5 modelling and dominated by GHG forcing show increased mean rainfall by the end of the 21st century.

There is *very high confidence* (*robust evidence, high agreement*) of a negative trend of summer monsoon rainfall over the second half of the 20th century averaged over all of India. There is *medium agreement* over trends at the regional level owing to uncertainty among observational products, which hinders model evaluation, downscaling and assessment of changes to extremes. There is *high confidence* (*robust evidence*, *medium agreement*) that anthropogenic aerosol emissions over the Northern Hemisphere and internal variability have contributed to the negative trend, while there is *high confidence* (*robust evidence*, *medium agreement*) that Indian summer monsoon rainfall will increase at the end of the 21st century in response to increased GHG forcing, due to the dominance of thermodynamic mechanisms. No contradictory evidence is found from downscaling methods. The contrast between declining rainfall in the observational record and long-term future increases can be explained using multiple lines of evidence. They are not contradictory since they are attributable to different mechanisms (primarily aerosols and greenhouse gases, respectively). The long-term future changes are generally consistent across global (including at high resolution) and regional climate models, and supported by theoretical arguments; furthermore, while there are subtle differences found in past periods with a climate similar to the future climate (the mid-Holocene), different physical mechanisms at play suggest that paleoclimate evidence does not reduce confidence in the future projections. In the near term, there is *high confidence* that internal variability will dominate.

10.6.4 Mediterranean Summer Warming

10.6.4.1 Motivation and regional context

The Mediterranean region is loosely denoted as the region that surrounds the Mediterranean Sea, and it is characterized by complex orography and strong land-sea contrasts. The region contains a dense and growing human population, with large regional differences: whereas the population of the European Mediterranean countries has been relatively stable or even declining during the past decades, the population of countries in Mediterranean areas of the Middle East and North Africa has quadrupled between 1960 and 2015, and the degree of urbanization has risen from 35 to 64% during the same period (Cramer et al., 2018) and during the more recent period 2000-2020 the urban expansion rate has exceeded 5% (Kuang et al., 2021).

The Mediterranean region has experienced significant climate variability over recent decades and has been affected in particular by severe heatwaves and droughts (Hoegh-Guldberg et al. (2018); Sections 8.3, 11.3, 11.6 and 12.4). Increasing summer temperatures will enhance the frequency and intensity of such extreme events and will cause additional environmental and socio-economic pressure on the region.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.6.4.2 The region's climate

The Mediterranean has a heterogeneous climate that is partly semi-arid, especially along the southern coast of the Mediterranean Sea (Lionello et al., 2012). It is characterized by mild humid winters and dry warm or hot summers, which are associated with large scale subsidence that is partly related to the downward branch of the Hadley circulation. Other factors affecting the Mediterranean circulation include the monsoon heating over Asia (Rodwell and Hoskins, 1996; Cherchi et al., 2014; Ossó et al., 2019) and circulation anomalies induced by topography (Simpson et al., 2015). Seasonal and interannual variability is strongly linked to natural modes of variability (Section 10.6.4.4). The Mediterranean Sea acts as an evaporation source that dominates the regional hydrological cycle, which is characterized by local cyclogenesis and a separate branch of the mid-latitude storm track (Lionello et al., 2016). It also affects remote locations such as the Sahel (Park et al., 2016; Section 10.4.2.1). Strong storms can develop over the Mediterranean: among these, Medicanes are particularly destructive and exhibit several similarities with tropical cyclones (Cavicchia et al., 2014; Kouroutzoglou et al., 2015; Gaertner et al., 2018). The Mediterranean region is also characterized by strong land-atmosphere coupling and feedbacks (Seneviratne et al., 2006) generating prolonged droughts and intense heatwaves, which can also affect continental Europe (Zampieri et al., 2009). Other aspects of Mediterranean climate include regional winds, which can be very strong due to the channelling effect (Obermann et al., 2018) and extreme rainfall during autumn (Ducrocq et al., 2014; Ribes et al., 2019).

10.6.4.3 Observational issues

The Mediterranean region spans a wide variety of countries and economies. This has led to large differences in the existence and availability of observational records, with the southern part of the area being sparsely covered by meteorological stations (Figure 10.20b). Consequently, basin-wide, homogeneous, quality controlled observational datasets are lacking, especially before the advent of substantial satellite observations in the 1970s. Observational uncertainties exist also for those regions that are covered by high quality networks such as ECA&D (Flaounas et al., 2012).

Large differences of up to 7°C between the CRU and UDEL datasets have been found especially over mountainous areas, such as the Atlas in Morocco (Zittis and Hadjinicolaou, 2017; Strobach and Bel, 2019). Bucchignani et al., (2016b, 2016a) compared three different datasets (CRU, UDEL, and MERRA) with the available ground observations and found that although the geographical distribution of the bias is qualitatively similar for the three datasets, differences exist, with the absolute bias being generally lower in MERRA especially over North Africa during the summer and winter season. There is *high confidence* that the sparse monitoring network in parts of the Mediterranean region strongly increases the uncertainty across different gridded datasets (Section 10.2.2.3, Figure 10.20b,c).

10.6.4.4 Relevant anthropogenic and natural drivers

The Mediterranean summer climate is affected by large-scale modes of natural variability, the most dominant being the NAO (Annex IV) in winter and the summer NAO in summer (Folland et al., 2009; Bladé et al., 2012), although regional differences exist. The influence of those modes of variability over the eastern Mediterranean is recognized by some studies (Chronis et al., 2011; Kahya, 2011; Black, 2012; Bladé et al., 2012), but disputed by others (Ben-Gai et al., 2001; Ziv et al., 2006; Donat et al., 2014; Turki et al., 2016; Zamrane et al., 2016; Han et al., 2019). During positive summer NAO phase, associated with an upper-level trough over the Balkans, the Mediterranean is anomalously wet (Bladé et al., 2012). Drivers of Mediterranean climate variability include modes of variability such as the AMV (Sutton and Dong, 2012) and the Asian monsoon (Rodwell and Hoskins, 1996; Logothetis et al., 2020). In addition, the increase of GHGs (e.g., Zittis et al., 2019), the decrease of anthropogenic aerosols over Europe and the Mediterranean since the 1980's resulting from air pollution policies (Turnock et al., 2016), and anthropogenic land-use change (Millán, 2014; Cramer et al., 2020) have been shown to be linked to the regional warming. The role

ACCEPTED VERSION SUBJECT TO FINAL EDITING

of the zonal averaged circulation as a driver for the Mediterranean climate has been stressed by (Garfinkel et al., 2020).

The attribution of observed Mediterranean summer warming to above drivers and implications for future projections will be discussed in Sections 10.6.4.5 and 10.6.4.6.

10.6.4.5 Model simulation and attribution over the historical period

Observational datasets show large agreement on the historical (1960-2014) temperature evolution at basin-wide scale (Figure 10.20e), with an enhanced warming since the 1990's, and the early decades of the 21st century being on average approximately more than 1°C warmer than late 19th century levels (van der Schrier et al., 2013; Cramer et al., 2018; Lionello and Scarascia, 2018; Figure 10.20e). Over recent decades, the surface air temperature of the Mediterranean including the Mediterranean Sea has warmed by around 0.4°C per decade (Macias et al., 2013). Observed trends over land show large geographical heterogeneity (Figure 10.20d) and notable differences exist amongst different datasets at grid point scale (Figure 10.20c; Qasmi et al., 2021).

Several mechanisms have been proposed for the enhanced Mediterranean warming, although their relative importance and the possible interplay between them are not fully understood. Circulation changes might have contributed to this enhanced warming (Figure 10.20a). Sutton and Dong (2012) argued that the AMV induced a shift around the 1990s towards warmer southern European summers. This mechanism is associated with a linear baroclinic atmospheric response to the AMV-related surface heat flux. Also O'Reilly et al. (2017) related warm summer decades to the AMV, but the connection was shown to be mainly thermodynamic. Qasmi et al. (2021) estimate an increase in Mediterranean summer temperature of 0.2-0.8°C during a positive AMV.

Increased warming over land compared to the sea is expected due to the lapse-rate changes associated with tropospheric moisture contrasts (Kröner et al., 2017; Byrne and O'Gorman, 2018; Brogli et al., 2019a; Figure 10.20a). Enhanced land-sea temperature contrast leads to relative humidity and soil moisture feedbacks (Rowell and Jones, 2006), the latter also depending on weather regimes (Quesada et al., 2012). The globally enhanced land-sea contrast in near surface temperature is also a robust result in CMIP5 and CMIP6 models (section 4.5.1.1).

Due to its semi-arid climate, strong atmosphere-land coupling has contributed to the larger increase of mean summer temperature compared to the increase of annual mean temperature (Seneviratne et al., 2006). In particular, during drought spells, limits to evaporation due to low soil moisture provide a positive feedback and enhances the intensity of heat waves (Lorenz et al., 2016; Box 11.1). By comparing reanalysis-driven RCM simulations with observations, Knist et al. (2017) found that RCMs are able to reproduce soil moisture interannual variability, spatial patterns, and annual cycles of surface fluxes over the period 1990–2008, revealing a strong land-atmosphere coupling especially in southern Europe in summer. In addition cloud feedbacks can modulate the Mediterranean summer temperature (Mariotti and Dell'Aquila, 2012).

The observed trends over 1901–2010 are outside the range of internal variability shown in CMIP5 pre-industrial control experiments and consistent with, or greater than those simulated by experiments including both anthropogenic and natural forcings (Knutson et al., 2013) and therefore partly attributable to anthropogenic forcing. The decrease of anthropogenic aerosols over Europe including the Mediterranean resulting from European de-industrialisation and air pollution policies (Turnock et al., 2016) has been highlighted as an important contributor to the observed warming (Ruckstuhl et al., 2008; Philipona et al., 2009; Laat and Crok, 2013; Nabat et al., 2014; Besselaar et al., 2015; Dong et al., 2017; Boé et al., 2020a). Pfeifroth et al. (2018) argue that this brightening is mainly due to cloud changes caused by the indirect aerosol effect with a minor role for the direct aerosol effect, in contrast to Nabat et al. (2014) and Boers et al. (2017) who attribute it to the direct aerosol effect. Using model sensitivity experiments, Nabat et al., (2014) also associated the increase in Mediterranean SST since 1980-2012 with the decrease in aerosol concentrations (Atlas 8.2, 8.3, 8.5).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Over the period 1960-2014, observed trends over land are consistent with those of most of the multi-model or SMILEs ensembles (Figure 10.20f), although large differences exist for individual models and ensemble members. The modelled ensemble-mean trends show large geographical variations; generally, both global and regional models often underestimate the observed trend especially over part of North Africa, Italy, the Balkans and Turkey. The cold bias in GCMs is related to simulated SLP trends that are anti-correlated to the observed trend, which is probably due to systematic model errors (Boé et al., 2020b). Biases in the simulation of soil-moisture and cloud-cover might also have contributed to the underestimation of the warming trend in GCMs (van Oldenborgh et al., 2009). The CORDEX results (at both 0.44 and 0.11 degree resolution) show consistently smaller values than those in GCMs and the available data sets (Figure 10.20g; Vautard et al., (2020)). This is partly due to the overestimation in the temperature evolution before 1990 (Figure 10.20e), possibly because of differences in the aerosol forcing (Boé et al., 2020a), although the driving GCMs also have a cold bias (Vautard et al., 2020). Cold biases for recent decades are also found in Med-CORDEX simulations (Dell'Aquila et al., 2018) and by RCM simulations over the southern part of the Mediterranean, Middle East and North Africa region (Almazroui, 2016; Almazroui et al., 2016b, 2016a; Ozturk et al., 2018; Zittis and Hadjinicolaou, 2017), although higher resolution, new bare soil albedo and modified aerosol parameterization significantly improve the results (Bucchignani et al., 2016b, 2016a, 2018). Despite large differences in the multi-model mean trend (Figure 10.20g), in most of the land points the observed trend lies within the model range in all ensembles. For the SST bias exhibited by coupled RCMs the choice of driving GCM has the largest impact (Darmaraki et al., 2019; Soto-Navarro et al., 2020).

10.6.4.6 Future climate information from global simulations

The Mediterranean is expected to be one of the most prominent and vulnerable climate change hotspots (Diffenbaugh and Giorgi, 2012). CMIP5, CMIP6, HighResMIP and CORDEX (Section 10.6.4.7) simulations all project a future warming for the 21st century that ranges between 3.5 and 8.75 °C for RCP8.5 at the end of this century for those ending at 2100 (Figure 10.21a,b)). CMIP6 results project more pronounced warming than CMIP5 for a given emission scenario and time period (Figure 10.21c; Coppola et al., 2020b). However, when analysing the Mediterranean warming in terms of mean global warming levels, the two ensembles largely agree showing that summer warming is projected to reach values up to 40-50% larger than the global annual warming, largely independent of models and emission scenarios (Figure 10.21d). Large regional differences exist, with enhanced warming projected over Turkey, the Balkans, the Iberian Peninsula and North African regions (Almazroui et al., 2020a; Figures 10.14a, 10.21c) and reaching, locally, values of up to double the global mean (Lionello and Scarascia, 2018). The enhanced summer warming also increases the amplitude of the seasonal cycle (Yettella and England, 2018).

As noted in Section 10.6.4.4, the Mediterranean summer climate is affected by large-scale circulation patterns, of which the summer NAO is the most important (Folland et al., 2009; Bladé et al., 2012). Barcikowska et al. (2020) highlight the importance of correctly simulating the summer NAO impact on the Mediterranean climate, as it partly offsets the anthropogenic warming signal in the western and central Mediterranean.

Climate models project a reduction in precipitation in all seasons, and a northward and eastward expansion of the Mediterranean climate, with the affected areas becoming more arid with an increased summer drying (Alessandri et al., 2015; Mariotti et al., 2015; Rajczak and Schär, 2017; Waha et al., 2017; Barredo et al., 2018; Lionello and Scarascia, 2018; Spinoni et al., 2018, 2020; Atlas 8.5). The drying can contribute to the enhanced warming by land-surface feedbacks (Whan et al., 2015; Lorenz et al., 2016; Russo et al., 2019). A negative feedback to this dryness induced warming might be provided by an enhanced moisture transport into the dry area associated with the dynamical response of the atmosphere (Zhou et al., 2021). Due to the arid climate, no positive soil moisture-temperature feedback is found over the North African regions of the Mediterranean, where the surface energy budget is mostly governed by radiative cooling (Lelieveld et al., 2016), implying that soil-moisture feedbacks are not contributing to enhanced warming over those regions.

Over the Mediterranean region, daily maximum temperature is projected to increase more than the daily

ACCEPTED VERSION SUBJECT TO FINAL EDITING

minimum. Consequently, the difference between daytime maxima and night-time minima is expected to increase, particularly in summer (Lionello and Scarascia, 2018). Temperature extremes will be affected as well, with a dramatic increase in the number of warm days and reduction of cold nights (Lionello and Scarascia, 2020; Section 11.9). The Mediterranean summer warming will also increase the frequency and intensity of heatwaves (Section 11.9).

[START FIGURE 10.20 HERE]

Figure 10.20: Aspects of Mediterranean summer warming. (a) Mechanisms and feedbacks involved in enhanced Mediterranean summer warming. (b) Locations of observing stations in E-OBS and (Donat et al., 2014). (c) Differences in temperature observational data sets (NOAA Global Temp, Berkeley Earth, CRUTEM4 and GISTEMP) with respect to E-OBS for the land points between the Mediterranean Sea and 46°N and west of 30°E. (d) Observed summer (June to August) surface air temperature linear trends (°C decade^{-1}) over the 1960–2014 period from Berkeley Earth. (e) Time series of area averaged Mediterranean (25°N–50°N, 10°W–40°E) land point summer temperature anomalies (°C, baseline 1995–2014). Dark blue, brown and turquoise lines show low-pass filtered temperature of Berkeley Earth, CRU TS and HadCRUT5, respectively. Orange, light blue and green lines show low-pass filtered ensemble means of HighResMIP (4 members), CORDEX EUR-44 (20 members) and CORDEX EUR-11 (37 members). Blue and red lines and shadings show low-pass filtered ensemble means and standard deviations of CMIP5 (41 members) and CMIP6 (36 members). The filter is the same as the one used in Figure 10.10. (f) Distribution of 1960–2014 Mediterranean summer temperature linear trends (°C decade^{-1}) for observations (black crosses), CORDEX EUR-11 (green circles), CORDEX EUR-44 (light blue circles), HighResMIP (orange circles), CMIP6 (red circles), CMIP5 (blue circles) and selected SMILEs (grey box-and-whisker plots, MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF). Ensemble means are also shown. CMIP6 models showing a very high ECS (Box. 4.1) have been marked with a black cross. All trends are estimated using ordinary least-squares and box-and-whisker plots follow the methodology used in Figure 10.6. (g) Ensemble mean differences with respect to the Berkeley Earth linear trend for 1960–2014 (°C decade^{-1}) of CMIP5, CMIP6, HighResMIP, CORDEX EUR-44 and CORDEX EUR-11. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[START FIGURE 10.21 HERE]

Figure 10.21: Projected Mediterranean summer warming. (a) Time series of area averaged Mediterranean (25°N–50°N, 10°W–40°E) land point summer surface air temperature anomalies (°C, baseline period is 1995–2014). Orange, light blue and green lines show low-pass filtered ensemble means of HighResMIP (highres-future, 4 members), CORDEX EUR-44 (RCP8.5, 20 members) and CORDEX EUR-11 (RCP8.5, 37 members). Blue and dark red lines and shadings show low-pass filtered ensemble means and standard deviations of CMIP5 (RCP8.5, 41 members) and CMIP6 (SSP5-8.5, 36 members). The filter is the same as the one used in Figure 10.10. The box-and-whisker plots show long term (until 2081-2100) temperature changes of different CMIP6 scenarios with respect to the baseline period (SSP1-2.6 in dark blue, SSP2-4.5 in yellow, SSP3-7.0 in red, SSP5-8.5 in dark red). (b) Distribution of 2015–2050 Mediterranean summer temperature linear trends (°C decade^{-1}) for CORDEX EUR-11 (RCP8.5, green circles), CORDEX EUR-44 (RCP8.5, light blue circles), HighResMIP (highres-future, orange circles), CMIP6 (SSP5-8.5, dark red circles), CMIP5 (RCP8.5, blue circles) and selected SMILEs (grey box-and-whisker plots, MIROC6, CSIRO-Mk3-6-0 and MPI-ESM). Ensemble means are also shown. CMIP6 models showing a very high ECS (Box 4.1) have been marked with a black cross. All trends are estimated using ordinary least-squares and box-and-whisker plots follow the methodology used in Figure 10.6. (c) Projections of ensemble mean 2015–2050 linear trends (°C decade^{-1}) of CMIP5 (RCP8.5), CORDEX EUR-44 (RCP8.5), CORDEX EUR-11 (RCP8.5), CMIP6 (SSP5-8.5) and HighResMIP (highres-future). All trends are estimated using ordinary least-squares. (d) Projected Mediterranean summer warming in comparison to global annual mean warming of CMIP5 (dashed lines, RCP2.6 in dark blue, RCP4.5 in light blue, RCP6.0 in orange and RCP8.5 in red) and CMIP6 (solid lines, SSP1-2.6 in dark blue, SSP2-4.5 in yellow, SSP3-7.0 in red and SSP5-8.5 in dark red) ensemble means. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

10.6.4.7 Future climate information from regional downscaling

To unravel the complex interactions and feedbacks over the region on a range of spatial and temporal scales, regional downscaling projects are being developed to provide more comprehensive and detailed information on the future of the Mediterranean. The importance of regional downscaling for investigating the subregional details caused by the complex morphology of the Mediterranean region is a well-known issue in the literature (Planton et al., 2012), which has been addressed in many studies since AR5. Recent examples of dynamical downscaling are EURO-CORDEX (Jacob et al., 2014) and Med-CORDEX (Ruti et al., 2016; Somot et al., 2018), but earlier activities have included ENSEMBLES (Déqué et al., 2012; Fernández et al., 2019), PRUDENCE (Christensen et al., 2002), CIRCE (Gualdi et al., 2013) and ESCENA (Jiménez-Guerrero et al., 2013).

From an analysis of CORDEX results, studies showed that southern Europe is projected to face a robust non-linear increase in temperature larger than the global mean (Zittis et al., 2019), EURO-CORDEX projections, that are driven by CMIP5 GCMs, project a less pronounced warming thanthat of CMIP6 (Coppola et al., 2020a; Figure 10.21c). The non-linear increase is especially evident for both hot and cold extremes (Maule et al., 2017; Jacob et al., 2018; Kjellström et al., 2018; Section 11.9). In particular, Dosio and Fischer (2018) showed that in many places in southern Europe and the Mediterranean, the increase in the number of nights with temperature above 20°C is more than 60% larger under 2°C warming compared to 1.5°C. Over the region, the projected temperature increase, including a higher probability of severe heat waves (Russo et al., 2015), is accompanied by a reduction in precipitation (Jacob et al., 2014; Dosio, 2016; Rajczak and Schär, 2017), resulting in projected increases of drought frequency and severity (Spinoni et al., 2018, 2020; Raymond et al., 2019). Also, the frequency and severity of marine heat waves of the Mediterranean Sea are projected to increase (Darmaraki et al., 2019; Section 12.4, Atlas 8.4).

Only a limited number of RCM simulations for the MENA domain are currently available. For the southern and eastern Mediterranean, they project a mean warming ranging from 3°C for RCP4.5 to 9°C for RCP8.5 at the end of this century compared to its beginning (Bucchignani et al., 2018; Ozturk et al., 2018). The frequency and duration of heatwaves and annual number of extremely hot days (i.e., those with maximum temperature > 50°C) in the southern Mediterranean will increase substantially. For 2070-2099 with respect to 1971-2000 the latter might even reach 70 days for RCP8.5 (Lelieveld et al., 2016; Almazroui, 2019; Driouech et al., 2020; Varela et al., 2020).

Despite the large efforts of these regional downscaling projects, the GCM-RCM matrix is still sparse and lacking a systematic design to explore the uncertainty sources (e.g., GCM, RCM, scenario, resolution) (Section 10.3). Focusing on the Iberian peninsula, Fernández et al. (2019) argued that the driving GCM is the main contributor to uncertainty in the ensemble. Physically consistent but implausible temperature changes in RCMs can occur. An example is a strong temperature increase over the Pyrenees due to excessive snow cover in the present climate (Fernández et al., 2019). Based on an older set of RCM simulations (ENSEMBLES), Déqué et al. (2012) also argued that the largest source of uncertainty in the temperature response over Southern Europe is the choice of the driving GCM (whereas for summer precipitation the choice of the RCM dominates the uncertainty). Finally, Boé et al. (2020) found that over a large area of Europe, including parts of the Mediterranean, RCMs project a summer warming 1.5–2°C colder than in their driving GCMs for the end of the 21st century. This is caused by differences in solar radiation related to the absence of time-varying anthropogenic aerosols in RCMs (Boé et al., 2020a; Gutiérrez et al., 2020), which also affects the noted differences in cloud cover between GCMs and RCMs (Bartók et al., 2017).

Statistical downscaling studies for the Mediterranean confirm the results from GCM and RCM studies, with large agreement among future projections showing lower rates of warming in winter and spring, and, in most cases, higher ones in summer and autumn (Jacobeit et al., 2014).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

10.6.4.8 Storyline approaches

The atmospheric circulation is influenced by large-scale, often slowly varying components of the climate system, such as ocean, sea ice and soil moisture. Historical and future changes of the atmospheric circulation depend, among other factors, on how these drivers have changed and will change. Zappa and Shepherd (2017) have analysed this for the Mediterranean region and developed a set of storylines based on different plausible evolutions of those drivers and their impact on the Mediterranean winter climate. Important identified drivers during winter are tropical and polar amplification of global warming and the polar stratospheric vortex (Manzini et al., 2014; Simpson et al., 2018), with implications for precipitation. Zappa (2019) discusses the relative amplitude of tropical and Arctic warming, response of the AMOC, patterns of Pacific SST change, and changes in stratospheric vortex strength as possible drivers of the Mediterranean summer climate and stresses that given the present state of knowledge, alternative storylines based on these drivers should be considered as equally plausible future manifestations of regional climate change. Brogli et al. (2019a, 2019b) and Kröner et al. (2017) have revealed thermodynamic processes, lapse rate, and circulation as important drivers for Mediterranean summer climate.

Low-likelihood high-impact events might affect future Mediterranean climate. An example of such an event is the collapse of the AMOC (Weijer et al., 2019), that would bring widespread cooling over the Northern Hemisphere. For the Mediterranean this is estimated to be a few degrees Celsius during summer in the case of a total collapse (Jackson et al., 2015).

10.6.4.9 Climate information distilled from multiple lines of evidence

There is *very high confidence (high agreement, robust evidence)* that the Mediterranean region has experienced a summer temperature increase in recent decades that is faster than the increase for the Northern Hemisphere summer mean. There is also *very high confidence* (*high agreement, robust evidence*) that the projected Mediterranean summer temperature increase will be larger than the global warming level, with an increase in the frequency and intensity of heat waves.

Traditionally, the distillation process to produce contextualised, policy relevant information has taken place at regional or national level. For example, the potential effects of climate change on public health are discussed in several national climate change and adaptation reports (Bruci et al., 2016; MoARE, 2016; MoE, 2016; MoEP, 2018; MoEU, 2018). Although these reports are extremely helpful and widely used for the development of national adaptation policies, they are often based on non-comprehensive and heterogeneous sources of climate information (e.g., MEEN, 2018; MoE/UNDP/GEF, 2019): for instance, future climate change projections are based on a limited number of socio-economic scenarios and climate model simulations, which are also often not evaluated comprehensively (e.g., Bruci ED, 2016; MoARE, 2016; MoEU, 2018). In addition, these reports are often not peer-reviewed, not available in English, and mainly limited to the country level, thus making it difficult to compare the details of the climate information across them.

[START BOX 10.3 HERE]

BOX 10.3: Urban Climate: Processes and Trends

Urban areas have special interactions with the climate system that produce heat islands. This box presents information about these processes, how they are parameterized in climate modules, and on the role of urban monitoring networks. A discussion on the observed climate trends and climate change projections for urban areas follows.

Urban Heat Island

During night-time, urban centres are often several degrees warmer than the surrounding rural area, a phenomenon known as the night-time canopy urban heat island effect (Bader et al., 2018; Kuang, 2019; Li et

ACCEPTED VERSION SUBJECT TO FINAL EDITING

al., 2019, 2020d). While green and blue infrastructures can mitigate the urban heat island effect, three main factors contribute to its development (Hamdi et al., 2020; Masson et al., 2020): 1) three-dimensional urban geometry including building density and plan area, street aspect ratio and building height, 2) thermal characteristics of impervious surfaces, and 3) anthropogenic heat release, either from building energy consumption, especially waste heat from air conditioning systems, or as direct emissions from industry, traffic, or human metabolism (Ichinose et al., 1999; Sailor, 2011; de Munck et al., 2013; Bohnenstengel et al., 2014; Chow et al., 2014; Salamanca et al., 2014; Dou and Miao, 2017; Ma et al., 2017a; Chrysoulakis et al., 2018; Takane et al., 2019). Urban heat island magnitude is also affected by aerosols due to air pollution in urban areas (Cheng et al., 2020; Han et al., 2020) and by local background climate (Zhao et al., 2014; Ward et al., 2016).

Monitoring Network

Long-term climate datasets (a year or more) at the small spatial scales required to resolve processes of interest for cities (<1 km) are scarce (Bader et al., 2018; Caluwaerts et al., 2020). Moreover, urban observation sites often represent only parts of the urban environment and are suboptimal for detecting urban effects (e.g., sites in city parks). Recently, city-scale climate monitoring networks as well as satellite and ground-based remote sensing are being used (though still missing in global south cities; Technical Annex I), enhancing our understanding of the urban microclimate and its interaction with climate change, and providing key information for users (Chen et al., 2012a; Barlow et al., 2017; Bader et al., 2018). It has been found that harmonization of collection practices, instrumentation, station locations, and quality control methodologies across urban environments needs improvement to facilitate collaborative research (Muller et al., 2013; Barlow et al., 2017). Real time crowdsourcing data is becoming available (Section 10.2.4). The urban climate community is making efforts to understand how these methods can complement traditional datasets (Meier et al., 2017; Zheng et al., 2018; Langendijk et al., 2019a; Venter et al., 2020).

Urban Modules in Climate Models

Exchanges of heat, water and momentum between the urban surface and its overlying atmosphere are calculated using specific surface-atmosphere exchange schemes. Three different schemes, here in order of increasing complexity, can be distinguished (Masson, 2006; Grimmond et al., 2010, 2011; Chen et al., 2011; Best and Grimmond, 2015): 1) In the slab or bulk approach, the three-dimensional city structure is not resolved but cities are represented by modifying soil and vegetation parameters within land surface models, increasing roughness length and displacement height (e.g., Best et al., 2006; Dandou et al., 2005; Liu et al., 2006; Seaman et al., 1989). The energy balance is often modified to account for the radiation trapped by the urban canopy, heat storage, evaporation and anthropogenic heat fluxes. 2) Single-layer urban canopy modules use a simplified geometry (urban canyon, with three surface types: roof, road and wall) that approximately capture the three-dimensional dynamical and thermal physical processes influencing radiative and energy fluxes (Masson, 2000; Kusaka et al., 2001). 3) Multi-layer urban canopy modules compute urban effects vertically, allowing a direct interaction with the planetary boundary layer (Brown, 2000; Martilli et al., 2002; Hagishima et al., 2005; Dupont and Mestayer, 2006; Hamdi and Masson, 2008; Schubert et al., 2012). Building-energy models that estimate anthropogenic heat from a building for given atmospheric conditions can be incorporated. Recent model development has focused on improving the representation of urban vegetation (Lee et al., 2016; Redon et al., 2017; Mussetti et al., 2020).

Global (McCarthy et al., 2010; Oleson et al., 2011; Zhang et al., 2013; Chen et al., 2016b; Katzfey et al., 2020; Sharma et al., 2020; Hertwig et al., 2021) and regional modelling groups (Kusaka et al., 2012b; McCarthy et al., 2012; Hamdi et al., 2014; Trusilova et al., 2016; Daniel et al., 2019; Halenka et al., 2019; Langendijk et al., 2019b) are beginning to implement these urban parameterizations within the land-surface component of their models. There is *very high confidence* (*robust evidence* and *high agreement*) that while all types of urban parameterizations generally simulate radiation exchanges in a realistic way, they have strong biases when simulating latent heat fluxes, though recent research incorporating in-canyon vegetation processes improved their performance. There is *medium confidence* (*medium evidence, high agreement*) (Kusaka et al., 2012a; McCarthy et al., 2012; Hamdi et al., 2014; Trusilova et al., 2016; Jänicke et al., 2017; Daniel et al., 2019) that a simple single-layer parameterization, is sufficient for the correct simulation of the urban heat island magnitude and its interplay with regional climate change.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Observed Trends

There is *medium evidence* but *high agreement* (Parker, 2010; Zhang et al., 2013; Chen et al., 2016b) that the global annual mean surface air temperature response to urbanization is negligible. There is very high confidence that the different observed warming trend in cities as compared to their surroundings can partly be attributed to urbanization (Box 10.3, Figure 1; Park et al., 2017).

[START BOX 10.3, FIGURE 1 HERE]

Box 10.3, Figure 1: Urban warming compared to global GHG-induced warming. (a) Change in the annual mean surface air temperature over the period 1950–2018 based on the local linear trend retrieved from CRU TS (°C per 68 years). This background warming is compared to the local warming that has been reported during 1950–2018 in the literature from historical urbanization. The relative share of the total warming as percentage between the urban warming and the surrounding warming is plotted in a circle for each city. This map has been compiled from a review study (Hamdi et al., 2020). (b) Low-pass filtered time series of the annual mean temperature (°C) observed in the urban station of Tokyo (red line) and the rural reference station in Choshi (blue line) in Japan. The filter is the same as the one used in Figure 10.10. (c) Uncertainties in the relative share of urban warming with respect to the total warming (%) related to the use of different global observational datasets: CRU TS (brown circles), Berkeley Earth (dark blue downward triangle), HadCRUT5 (cyan upward triangle), Cowtan Way (orange plus) and GISTEMP (purple squares). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END BOX 10.3, FIGURE 1 HERE]

There is *very high confidence* (*robust evidence* and *high agreement*) that the annual-mean minimum temperature is more affected by urbanization than the maximum temperature (Ezber et al., 2007; Fujibe, 2009; Hamdi, 2010; Elagib, 2011; Camilloni and Barrucand, 2012; Robaa, 2013; Hausfather et al., 2013; Argüeso et al., 2014; Alghamdi and Moore, 2015; Alizadeh-Choobari et al., 2016; Sachindra et al., 2016; Liao et al., 2017; Lokoshchenko, 2017; Wang et al., 2017a; Arsiso et al., 2018). Beside temperature, urbanization can induce an urban dryness island, which refers to lower relative humidity in cities than in nearby rural locations (Lokoshchenko, 2017; Bian et al., 2020) and the urban wind island, where slower wind speeds are observed in cities (Wu et al., 2017; Bader et al., 2018; Peng et al., 2018). There is *medium confidence* (*medium evidence* and *medium agreement*) (Schlünzen et al., 2010; Ganeshan et al., 2013; Ganeshan and Murtugudde, 2015; Haberlie et al., 2015; Daniels et al., 2016; Liang and Ding, 2017; McLeod et al., 2017; Li et al., 2020c) that cities induce increases in mean and extreme precipitation over and downwind of the city especially in the afternoon and early evening.

Climate Projections

Estimates of the urban heat island under further climate change are *very uncertain* because studies using different methods report contrasting results. However, there is *very high confidence* (*robust evidence* and *high agreement*) that the projected change of the urban heat island under climate change conditions is one order of magnitude less than the projected warming in both urban and rural areas under simulation constraints of no urban growth (Adachi et al., 2012; Arsiso et al., 2018; Früh et al., 2011; Hamdi et al., 2014; Hatchett et al., 2016; Hoffmann et al., 2018; Kusaka et al., 2012; McCarthy et al., 2010, 2012; Oleson, 2012; Oleson et al., 2011; Sachindra et al., 2016).

Combining climate change conditions together with urban growth scenarios, there is *very high confidence* (*robust evidence* and *high agreement*) that future urbanization will amplify the projected air temperature warming irrespective of the background climate (Georgescu et al., 2013; Argüeso et al., 2014; Mahmood et al., 2014; Doan et al., 2016; Kim et al., 2016; Kusaka et al., 2016; Grossman-Clarke et al., 2017; Kaplan et al., 2017; Li et al., 2018c) Urbanization will have a strong influence on minimum temperatures that could be locally comparable in magnitude to the global GHG-induced warming (Berckmans et al., 2019). There is *very high confidence* (*robust evidence* and *high agreement*) for the combination of future urban development and more frequent occurrence of extreme climatic events, such as heat waves (Hamdi et al., 2016; Bader et

ACCEPTED VERSION SUBJECT TO FINAL EDITING

al., 2018; He et al., 2021).

The choice of urban planning scenarios and RCM projections shows a large sensitivity during night-time, up to 0.6°C (Kusaka et al., 2016). The sensitivity is significantly less than the uncertainties arising from global emission scenarios or GCM projections. However, there is a large difference between RCM simulations with and without urban land use, indicating that this impact is comparable to the uncertainties related to the use of different GCM projections (Hamdi et al., 2014; Kusaka et al., 2016; Daniel et al., 2019). Therefore, impact assessments and adaptation plans for urban areas require high spatial resolution climate projections along with models that represent urban processes, ensemble dynamical and statistical downscaling, and local-impact models (Masson et al., 2014; Baklanov et al., 2018, 2020; Duchêne et al., 2020; Schoetter et al., 2020; Le Roy et al., 2021; Zhao et al., 2021).

[END CHAPTER BOX 10.3 HERE]

[START CROSS-CHAPTER BOX 10.4 HERE]

Cross-Chapter Box 10.4: Climate Change over the Hindu Kush Himalaya

Coordinators: Izuru Takayabu (Japan), Andrew Turner (UK), Zhiyan Zuo (China)
Contributors: Bhupesh Adhikary (Nepal), Muhammad Adnan (Pakistan), Muhammad Amjad (Pakistan), Subimal Ghosh (India), Rafiq Hamdi (Belgium), Akm Saiful Islam (Bangladesh), Richard G. Jones (UK), Martin Jury (Austria), Asif Khan (Pakistan), Akio Kitoh (Japan), Krishnan Raghavan (India), Lucas Ruiz (Argentina), Laurent Terray (France)

The Hindu Kush Himalaya (HKH) constitutes the largest glacierized region outside the poles and provides the headwaters for several major rivers (Sharma et al., 2019). Since the 1960s, the HKH has experienced significant trends in the mean and extremes of temperature and precipitation, accompanied by glacier mass loss and retreat, snowmelt and permafrost degradation (Yao et al., 2012a, 2012b; Azam et al., 2018; Bolch et al., 2019; Krishnan et al., 2019b, 2019a; Chug et al., 2020; Sabin et al., 2020). Observational uncertainty and lack of consistent, high-quality datasets hamper reliable assessments of climate change and model evaluation over several mountain areas, including the HKH (Section 10.2.2). This box assesses observed and projected climate change in the extended HKH (outline in Cross-Chapter Box 10.4, Figure 1a), in which we include the Tibetan Plateau (TP) and Pamir mountains.

Temperature trends

Little evidence was presented in the AR5 (IPCC, 2014) other than increased minimum and maximum temperature trends in the western Himalaya (Hartmann et al., 2013). SROCC assessed that HKH (named High Mountain Asia) surface-air temperature has warmed more rapidly than the global mean over recent decades (*high confidence*). Annual mean HKH surface air temperature increased significantly (about 0.1°C per decade) over 1901–2014 (Ren et al., 2017), although Cross-Chapter Box 10.4, Figure 1d shows an observational range of 0.20–0.25°C per decade over 1961–2014. There is a rising trend of extreme warm events and fewer extreme cold events over 1961–2015 (Krishnan et al., 2019b; Wester et al., 2019). However, summer cooling over the Karakoram (western HKH) was reported for 1960–2010 (Forsythe et al., 2017). A key relevant process is elevation-dependent warming (EDW; reviewed in Pepin et al., 2015), leading to warming of 2–2.5°C at 5000m over 1961–2006, but only 0.5°C at sea level (Xu et al., 2016). However, EDW behaviour appears to depend on region, time period and elevation (Guo et al., 2019a; Li et al., 2020a) and understanding is limited by the sparse observational network (You et al., 2020). Observational and model analyses have attributed EDW to GHG and black carbon emissions, accelerating warming by snow-albedo feedback (Ming et al., 2012; Gautam et al., 2013; Xu et al., 2016; Yan et al., 2016; Lau and Kim, 2018; Zhang et al., 2018b), or the more pronounced cooling effect of scattering aerosols at low elevations and stratospheric ozone depletion (Guo and Wang, 2012; Zeng et al., 2015). There is *high confidence* that the eastern and central HKH has exhibited rising temperatures (Cross-Chapter Box 10.4, Figure 1), with warming dependent on season and elevation. There is *high confidence* that much of the warming can be attributed to GHGs, but the effect of albedo has only *medium confidence*. There is *high*

ACCEPTED VERSION SUBJECT TO FINAL EDITING

confidence in more frequent extreme warm events and fewer extreme cold events over the eastern Himalayas in the last five decades.

[START CROSS-CHAPTER BOX 10.4, FIGURE 1 HERE]

Cross-chapter Box 10.4, Figure 1: Historical annual-mean surface air temperature linear trend (°C per decade) and its attribution over the Hindu Kush Himalaya (HKH) region. (a) Observed trends from Berkeley Earth (also showing the HKH outline), CRU TS (also showing the AR6 TIB outline, for ease of comparison to the Interactive Atlas), APHRO-MA and JRA-55 datasets over 1961–2014. (b) Models showing the coldest, median and warmest HKH temperature linear trends among the CMIP6 historical ensemble over 1961–2014. (c) Lowpass-filtered time series of annual-mean surface air temperature anomalies (°C, baseline 1961–1980) over the HKH region as outlined in panel (a), showing means of CMIP6 hist all-forcings (red), and the CMIP6 hist all-forcings sample corresponding to DAMIP experiments (pink), for hist-aer (grey) and hist-GHG (pale blue). Observed datasets are Berkeley Earth (dark blue), CRU (brown), APHRO-MA (light green) and JRA-55 (dark green). The filter is the same as that used in Figure 10.10. (d) Distribution of annual mean surface air temperature trends (°C per decade) over the HKH region from 1961 to 2014 for ensemble means, the aforementioned observed and reanalysis data (black crosses), individual members of CMIP6 hist all-forcings (red circles), CMIP6 hist-GHG (blue triangles), CMIP6 hist-aer (grey triangles), and box-and-whisker plots for the SMILEs used throughout Chapter 10 (grey shading). Ensemble means are also shown. All trends are estimated using ordinary least-squares regression and box-and-whisker plots follow the methodology used in Figure 10.6. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

[END CROSS-CHAPTER BOX 10.4, FIGURE 1 HERE]

Precipitation trends

Annual and summer precipitation over the central-eastern HKH show decreasing trends over 1979–2010 in multiple observed datasets, attributable to a weakening South Asian monsoon (Yao et al., 2012b; Palazzi et al., 2013; Roxy et al., 2015). There are contradictory trends in the western HKH (Azmat et al., 2017; Yadav et al., 2017; Li et al., 2018b; Meher et al., 2018), where most precipitation is associated with western disturbances on the subtropical westerly jet, but trends in western disturbance activity are unclear (Kumar et al., 2015; Hunt et al., 2019; Krishnan et al., 2019a). There has been an increased frequency and intensity of extreme precipitation over the central-western HKH but contrasting evidence in the east (Sheikh et al., 2015; Talchabhadel et al., 2018). The number of consecutive wet days has increased over 1961–2012, but with no uniform trend in consecutive dry days (Zhan et al., 2017). There is *medium confidence* that the eastern-central HKH has experienced decreased summer precipitation (Section 10.6.3). There is *medium confidence* in the increase of summer extreme precipitation over the western HKH.

Glacier trends

The SROCC assessed that snow cover has declined in duration, depth and accumulated mass at lower elevations in mountain regions, including the HKH (*high confidence*). Glaciers are losing mass (*very high confidence*) and permafrost is warming (*high confidence*) over high mountains in recent decades, and it is *very likely* that atmospheric warming is the main driver. A significant reduction in HKH glacier area has been observed since the 1970s, with smaller glaciers generally shrinking faster (e.g., Bolch et al., 2019). HKH glacier mass loss took place at the lowest rate among high mountain areas in the last 20 years, although with one of the largest total losses (Shean et al., 2020; Section 9.5.1.1; Figure 9.20). The highest mass-loss rates occurred in the eastern and northern HKH, while gains occurred in the west (e.g., Shean et al., 2020). Glacier mass gain has been coined as the “Karakoram anomaly” (Sections 9.5.1 and Section 8.3.1.7.1), explained by a combination of low temperature sensitivity of debris-covered glaciers, a decrease in summer air temperatures, and increased snowfall possibly linked to evapotranspiration from irrigated agriculture (You et al., 2017; Bolch et al., 2019; de Kok et al., 2020a; Farinotti et al., 2020). Meanwhile, increased air

ACCEPTED VERSION SUBJECT TO FINAL EDITING

temperature and decreased snowfall explain the glacier mass decrease elsewhere (Bonekamp et al., 2019; de Kok et al., 2020b; Farinotti et al., 2020; Shean et al., 2020). There is *high confidence* that glaciers in most HKH regions have thinned, retreated and lost mass since the 1970s.

Projections

In AR5, the HKH was projected to continue warming over the 21st century, faster than the *likely* ranges for the global mean and South Asia. New CMIP5 results show temperature increases across mountainous HKH by about 1–2°C (in some places in summer 4–5°C) during 2021–2050 compared to 1961–1990 (Shrestha et al., 2015). Projected warming differs by up to 1°C between east and west, with higher values in winter (Sanjay et al., 2017; see Interactive Atlas). Statistically significant mean warming (0.30–0.90°C per decade until the end of the 21st century) across all RCPs has been projected by CORDEX South Asia (Dimri et al., 2018). CMIP6 models report that northwestern South Asia, including the western Himalayas, are projected to experience temperature increases exceeding 6°C by the end of the 21st century under SSP5-8.5 relative to 1995–2014 (Almazroui et al., 2020c). Results from CMIP5, CMIP6 and CORDEX ensembles for different warming levels are shown in the Interactive Atlas and summarised in Figure Atlas.20. The HKH will *likely* continue warming in the coming decades.

(IPCC, 2018b) stated that heavy precipitation risk in high-elevation regions is projected to be higher at 2°C compared to 1.5°C of global warming (*medium confidence*). CMIP5 models project increased annual or summer monsoon precipitation over the HKH in the 21st century (Palazzi et al., 2015; Kitoh and Arakawa, 2016), intensifying by about 22% in the hilly south-eastern Himalaya and TP for the long term in RCP8.5, but with no trends in the western HKH (Rajbhandari et al., 2015; Krishnan et al., 2019a). CMIP6 projects an increase of winter precipitation over the western Himalayas, with a corresponding decrease in the east (Almazroui et al., 2020c). HKH projections are subject to large uncertainties in CMIP5 and CORDEX (Hasson et al., 2013, 2017; Mishra, 2015; Sanjay et al., 2017). CORDEX, in particular, has inherent limitations at reproducing the characteristics of summer monsoon rainfall variability (Singh et al., 2017). There is *medium confidence* that HKH precipitation will increase in the coming decades.

The SROCC assessed that glaciers will lose substantial mass (*high confidence*) and permafrost will undergo increasing thaw and degradation (*very high confidence*) over high mountain regions (including the HKH), with stronger changes for higher emission scenarios. Regional differences in warming and precipitation projections and glacier properties cause considerable differences in glacier response within High Mountain Asia (Kraaijenbrink et al., 2017). Glacier mass loss will accelerate through the 21st century, increasing with RCP after 2030 (Marzeion et al., 2014; Section 9.5.1.3). Loss of between 40 ± 25% to 69 ± 21 % of 2015 glacier volume is expected by 2100 in RCP 2.6 and RCP 8.5, respectively (Section 9.5.1.3; Figure 9.21). Glacier mass loss is expected due to decreased snowfall, increased snowline elevations and longer melt seasons. However, due to projection uncertainties, simplicity of the models, and limited observations, there is *medium confidence* in the magnitude and timing of glacier mass changes (Section 9.5.1.3). Glacier mass in HKH will decline through the 21st century (*high confidence*), more so under high-emissions scenarios.

[END CROSS-CHAPTER BOX 10.4 HERE]

10.7 Final remarks

The assessments in this chapter are based on a rapidly growing body of evidence from the peer-reviewed literature, most of which was not previously considered by IPCC reports. A number of challenges in the construction of regional climate change information have been identified:

- Limited climate monitoring in some regions impedes the full understanding of the relevant climate processes, an appropriate validation of model simulations, and the formulation of trustworthy regional climate information. Beyond temperature and precipitation, there is a shortage of observed variables needed for regional process understanding, attribution, and model development and validation, among others. Examples include surface evapotranspiration, soil moisture, radiation, wind and relative humidity, among many others identified by sectors sensitive to climate (Sections 10.2, 10.3 and 10.6).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

- Compared to the increasing number of large-scale evaluations, there is a shortage of process-based model evaluations at regional scales to assess the fitness of the chosen models for specific purposes (Sections 10.3 and 10.4).
- There is a general lack of studies of the simulation of large-scale, downscaling-relevant processes in global models to support the design of global/regional model matrices that both span a sufficiently large range of projection uncertainty and realistically represent the regional climate of interest. The fitness of statistical methods for regional climate change studies has received limited attention by the scientific community, while as in the case of global models, process-based evaluation has proven useful (Soares et al., 2019b). Studies of past changes and pseudo-reality studies to assess the predictors and model structures required for downscaling in a future climate are promising avenues (Section 10.3).
- Internal variability is a large contributor to climate uncertainty at regional scales, especially for extreme events. Further study of the processes governing regional internal variability, such as the modes of variability and the teleconnections that connect them to the regional variability, but also of the local processes and drivers involved, will help improve its understanding. The same applies to the validation of the simulated internal variability that underpins the trustworthiness of model-based climate information (Sections 10.3, 10.4 and 10.6, Cross-Chapter Box 10.1).
- Methodologies on how to propagate climate uncertainties from global and regional scales down to the human settlement scale are still under development. In some cases, bias-adjustment methods are used with substantial neglect of the physical processes involved (Section 10.3, Cross-Chapter Box 10.2).
- The production of regional climate information relies mainly on global and regional models that often do not incorporate human-controlled surface processes (urban parametrizations is one example) in their land-surface components. This limits the representation of uncertainties for climate information at the urban scale (Box 10.2, Cross-Chapter Box 10.2, Section 10.3).
- Literature plays a central role as a source for constructing regional climate change information. The amount of climate change literature available is unevenly distributed across the world, and large bodies of literature (e.g., local and regional reports) are often overlooked in the construction of climate information. Furthermore, research tends to focus on regions that attract the attention of the Global North so that climate aspects relevant to other regions may not receive sufficient attention for generating appropriate regional climate information (Sections 10.2, 10.3, 10.5 and 10.6).
- Governmental institutions producing regional and local climate information often use diverging approaches that are not necessarily coherent with each other. Coherency could be improved by implementing a quality control system and a traceability solution for the sources of the information. Collective work with the social sciences and humanities will improve the communication, perception and response to regional climate information and help translate user requirements (Sections 10.5 and 10.6).
- There is a shortage of regional climate change studies distilling multiple lines of evidence. Most studies rely on either global models or downscaled global models, with an increasing number of studies focusing on the use of emulators and the selection and combination of models. However, there are limited studies distilling this information with a wider range of lines of evidence that includes observations, process understanding, attribution, and hierarchies of models (Sections 10.3, 10.5 and 10.6).

Addressing these challenges could facilitate the assessment of both sources and methodologies that lead to an increased fitness and usefulness of regional climate information for a wide range of purposes.

Frequently Asked Questions

[START FAQ10.1 HERE]

FAQ 10.1: How can we provide useful climate information for regional stakeholders?

The world is physically and culturally diverse, and the challenges posed by climate change vary by region and location. Because climate change affects so many aspects of people's daily work and living, climate change information can help with decision-making, but only when the information is relevant for the people involved in making those decisions. Users of climate information may be highly diverse, ranging from professionals in areas such as human health, agriculture or water management to a broader community that experiences the impacts of changing climate. Providing information that supports response actions thus requires engaging all relevant stakeholders, their knowledge and their experiences, formulating appropriate information, and developing a mutual understanding of the usefulness and limitations of the information.

The development, delivery, and use of climate change information requires engaging all parties involved: those producing the climate data and related knowledge, those communicating it, and those who combine that information with their knowledge of the community, region or activity that climate change may impact. To be successful, these parties need to work together to explore the climate data and thus co-develop the climate information needed to make decisions or solve problems, distilling output from the various sources of climate knowledge into relevant climate information. Effective partnerships recognize and respond to the diversity of all parties involved (including their values, beliefs and interests), especially when they involve culturally diverse communities their indigenous and local knowledge of weather, climate and their society. This is particularly true for climate change – a global issue posing challenges that vary by region. By recognizing this diversity, climate information can be relevant and credible, most notably when conveying the complexity of risks for human systems and ecosystems and for building resilience.

Constructing useful climate information requires considering all available sources in order to capture the fullest possible representation of projected changes and distil the information in a way that meets the needs of the stakeholders and communities impacted by the changes. For example, climate scientists can provide information on future changes by using simulations of global and/or regional climate and inferring changes in the weather behaviour influencing a region. An effective distillation process (FAQ 10.1, Figure 1) engages with the intended recipients of the information, especially stakeholders whose work involves non-climatic factors, such as human health, agriculture or water resources. The distillation evaluates the accuracy of all information sources (observations, simulations, expert judgement), weighs the credibility of possible conflicting information, and arrives at climate information that includes estimating the confidence a user should have in it. Producers of climate data should further recognize that the geographic regions and time periods governing stakeholders' interest (for example, the growing season of an agricultural zone) may not align well with the time and space resolution of available climate data; thus additional model development or data processing may be required to extract useful climate information.

One way to distil complex information for stakeholder applications is to connect this information to experiences stakeholders have already had through storylines as plausible unfoldings of weather and climate events related to stakeholders' experiences. Dialogue between stakeholders and climate scientists can determine the most relevant experiences to evaluate for possible future behaviour. The development of storylines uses the experience and expertise of stakeholders, such as water-resource managers and health professionals, who seek to develop appropriate response measures. Storylines are thus a pathway through the distillation process that can make climate information more accessible and physically comprehensible. For example, a storyline may take a common experience like an extended drought, with depleted water availability and damaged crops, and show how droughts may change in the future, perhaps with even greater precipitation deficits or longer duration. With appropriate choices, storylines can engage nuances of the climate information in a meaningful way by building on common experiences, thus enhancing the information's usefulness.

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Forging partnerships among all involved with producing, exploring and distilling climate data into climate information is at the centre of creating stakeholder-relevant information. These partnerships can occur through direct interaction between climate scientists and stakeholders as well as through organizations that have emerged to facilitate this process, such as climate services, national and regional climate forums, and consulting firms providing specialized climate information. These so-called 'boundary organizations' can serve the varied needs of all who would fold climate information into their decision processes. All of these partnerships are vital for arriving at climate information that responds to physical and cultural diversity and to challenges posed by climate change that can vary region-by-region around the world.

[START FAQ 10.1, FIGURE 1 HERE]

FAQ 10.1, Figure 1: Climate information for decision makers is more useful if the physical and cultural diversity across the world is considered. The figure illustrates schematically the broad range of knowledge that must be blended with the diversity of users to distil information that will have relevance and credibility. This blending or distillation should engage the values and knowledge of both the stakeholders and the scientists. The bottom row contains examples of stakeholders' interests and is not all-inclusive. As part of the distillation, the outcomes can advance the U.N.'s Sustainable Development Goals, covered in part by these examples.

[START FAQ10.2 HERE]

FAQ 10.2: Why are cities hotspots of global warming?

Urban areas experience air temperatures that can be several degrees Celsius warmer than surrounding areas, especially during the night. This 'urban heat island' effect results from several factors, including reduced ventilation and heat trapping due to the close proximity of tall buildings, heat generated directly from human activities, the heat-absorbing properties of concrete and other urban building materials, and the limited amount of vegetation. Continuing urbanization and increasingly severe heatwaves under climate change will further amplify this effect in the future.

Today, cities are home to 55% of the world's population. This number is increasing, and every year cities welcome 67 million new residents, 90% of whom are moving to cities in developing countries. By 2030, almost 60% of the world's population is expected to live in urban areas. Cities and their inhabitants are highly vulnerable to weather and climate extremes, particularly heatwaves, because urban areas already are local hotspots. Cities are generally warmer – up to several degrees Celsius at night – than their surroundings. This warming effect, called the urban heat island, occurs because cities both receive and retain more heat than the surrounding countryside areas and because natural cooling processes are weakened in cities compared to rural areas.

Three main factors contribute to amplify the warming of urban areas (orange bars in FAQ 10.2, Figure 1). The strongest contribution comes from urban geometry, which depends on the number of buildings, their size and their proximity. Tall buildings close to each other absorb and store heat and also reduce natural ventilation. Human activities, which are very concentrated in cities, also directly warm the atmosphere locally, due to heat released from domestic and industrial heating or cooling systems, running engines, and other sources. Finally, urban warming also results directly from the heat-retaining properties of the materials that make up cities, including concrete buildings, asphalt roadways, and dark rooftops. These materials are very good at absorbing and retaining heat, and then re-emitting that heat at night.

The urban heat island effect is further amplified in cities that lack vegetation and water bodies, both of which can strongly contribute to local cooling (green bars in FAQ 10.2, Figure 1). This means that when enough vegetation and water are included in the urban fabric, they can counterbalance the urban heat island effect, to the point of even cancelling out the urban heat island effect in some neighbourhoods.

The urban heat island phenomenon is well known and understood. For instance, temperature measurements from thermometers located in cities are corrected for this effect when global warming trends are calculated. Nevertheless, observations, including long-term measurements of the urban heat island effect are currently too limited to allow a full understanding of how the urban heat island varies across the world and across different types of cities and climatic zones, or how this effect will evolve in the future.

As a result, it is hard to assess how climate change will affect the urban heat island effect, and various studies disagree. Two things are, however, very clear. First, future urbanization will expand the urban heat island areas, thereby amplifying future warming in many places all over the world. In some places, the nighttime warming from the urban heat island effect could even be on the same order of magnitude as the warming expected from human-induced climate change. Second, more intense, longer and more frequent heatwaves caused by climate change will more strongly impact cities and their inhabitants, because the extra warming from the urban heat island effect will exacerbate the impacts of climate change.

In summary, cities are currently local hotspots because their structure, material and activities trap and release heat and reduce natural cooling processes. In the future, climate change will, on average, have a limited effect on the magnitude of the urban heat island itself, but ongoing urbanization together with more frequent, longer and warmer heatwaves will make cities more exposed to global warming.

FAQ 10.2, Figure 1: Efficiency of the various factors at warming up or cooling down neighbourhoods of urban areas. Overall, cities tend to be warmer than their surroundings. This is called the 'urban heat island' effect. The hatched areas on the bars show how the strength of the warming or cooling effects of each factor varies depending on the local climate. For example, vegetation has a stronger cooling effect in temperate and warm climates. Further details on data sources are available in the chapter data table (Table 10.SM.11)

Figure 10.6: Illustration of some model biases in simulations performed with dynamical models. (a) Top row: Mean summer (June to August) near-surface air temperature (in °C) over the Mediterranean area in Berkeley Earth and respective mean bias for five multi-model historical experiments with GCMs (CMIP5, CMIP6 and HighResMIP) and RCMs (CORDEX EUR-44 and EUR-11) averaged between 1986–2005. Bottom row: Box-and-whisker plot shows spread of the 20 annual mean summer surface air temperature averaged over land areas in the western Mediterranean region (33°N–45°N, 10°W–10°E, black quadrilateral in the first panel of the top row) for a set of references and single model runs of the five multi-model experiments (one simulation per model) between 1986–2005. Additional observation and reanalysis data included in the bottom row are CRU TS, HadCRUT4, HadCRUT5, E-OBS, WFDE5, ERA5, ERA-Interim, CERA-20C, JRA-25, JRA-55, CFSR, MERRA2, MERRA. Berkeley Earth is

shown in the first box to the left. (b) as (a) but for precipitation rate (mm day^{-1}) and showing CRU TS in the first panel of the top row. Biases of the five multi-model experiments are shown with respect to CRU TS. Additional observation and reanalysis data included in the bottom row are GPCC, REGEN, E-OBS, GHCN, WFDE5, CFSR, ERA-Interim, ERA5, JRA-55, MERRA2, MERRA. CRU TS is shown in the first box to the left. All box-and-whisker plots show the median (line), and the interquartile range (IQR = Q3–Q1, box), with top whiskers extending to the last data less than Q3+1.5×IQR and analogously for bottom whiskers. Data outside the whiskers range appear as flyers (circles). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

Figure 10.7: Northern-Hemisphere blocking performance in historical coupled simulations for different multi-model ensembles. CMIP5/6: CMIP5 and CMIP6 DECK historical simulations, 1950-2005, LC/HC: Low/High-resolution simulations from the PRIMAVERA project, 1950–2014 following the hist-1950 experiment of the CMIP6 HighResMIP Protocol, (Haarsma et al., 2016). (top) blocking frequency, i.e. fraction of blocked days; (middle) root-mean-squared error in blocking frequency; (bottom) 90th percentile of blocking persistence, aggregated over an Atlantic domain (left, ATL: 90ºW–90ºE, 50º–75ºN) and a Pacific domain (right, PAC: 90ºE–270ºE, 50º–75ºN). Results are for boreal winter (DJF) and summer (JJA). Box-and-whisker plots for CMIP5/6 follow the methodology used in Figure 10.6 and show median (line), mean (triangle), and interquartile range (box) across 29 models for each ensemble. The reference estimate (ERA, asterisk) is from a 50-year reanalysis dataset that merged ERA-40 (1962–1978) and ERA-Interim (1979–2011) reanalyses. An estimate of internal variability for each metric (IV) is shown as a box-and-whisker plot over the asterisk and is obtained from a single-model ensemble (ECMWF-IFS high-resolution hist-1950 experiment, 6 x 65 years). For details on the methodology see (Schiemann et al., 2020). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

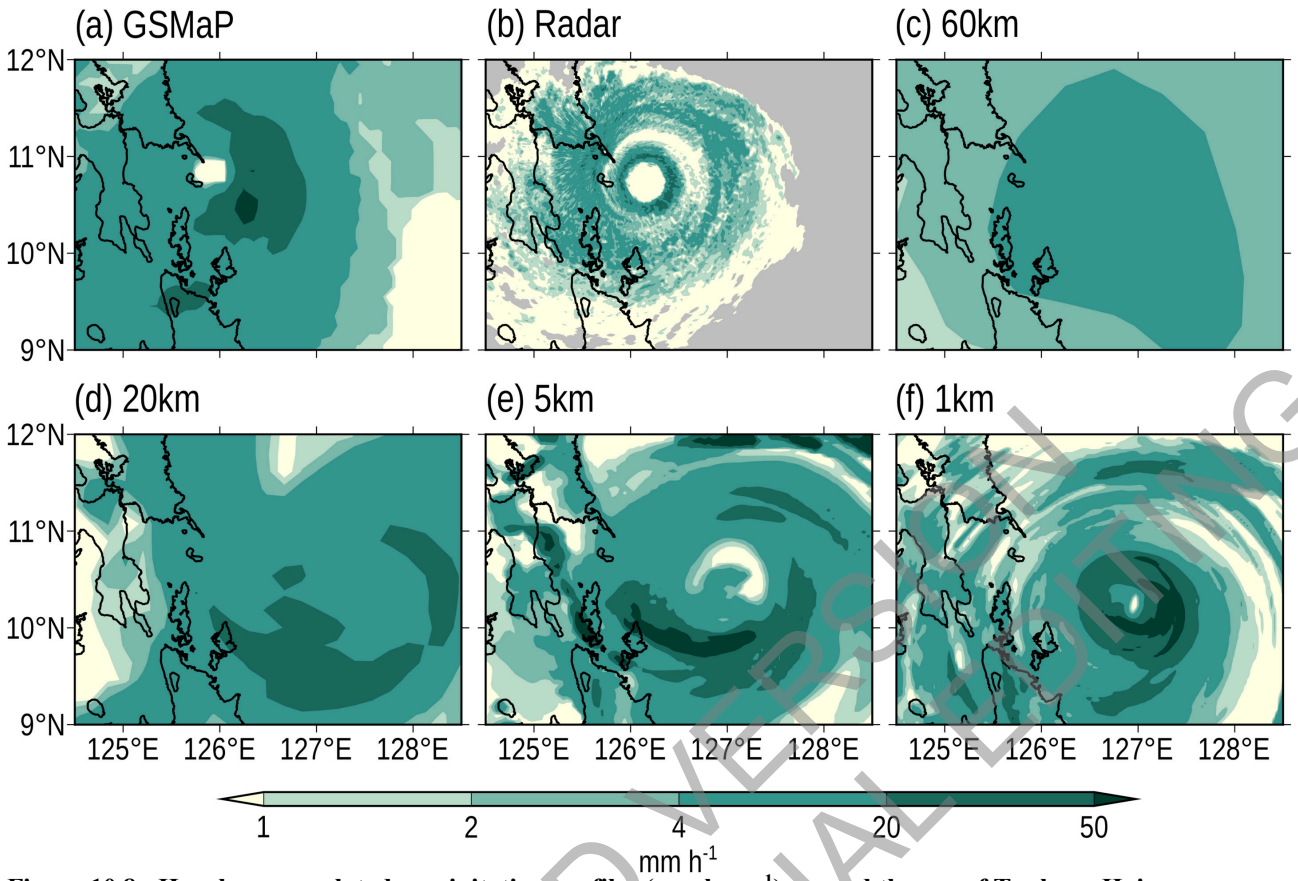

Figure 10.8: Hourly accumulated precipitation profiles (mm hour^{-1}) around the eye of Typhoon Haiyan. Cross-Chapter Box 10.2, Figure 1: Boreal spring (March to May) daily mean surface air temperature in the Sierra Nevada region in California. (a) Present climate (1981–2000 average, in °C) in the GFDL-CM3 AOGCM, interpolated to 8 km (left), GCM bias adjusted (using quantile mapping) to observations at 8 km resolution (middle) and WRF RCM at 3 km horizontal resolution (right). (b) Climate change signal (2081–2100 average minus 1981–2000 average according to RCP8.5, in °C) in the AOGCM (left), the bias adjusted AOGCM (middle) and the RCM (right). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11). Adapted from Maraun et al. (2017b).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

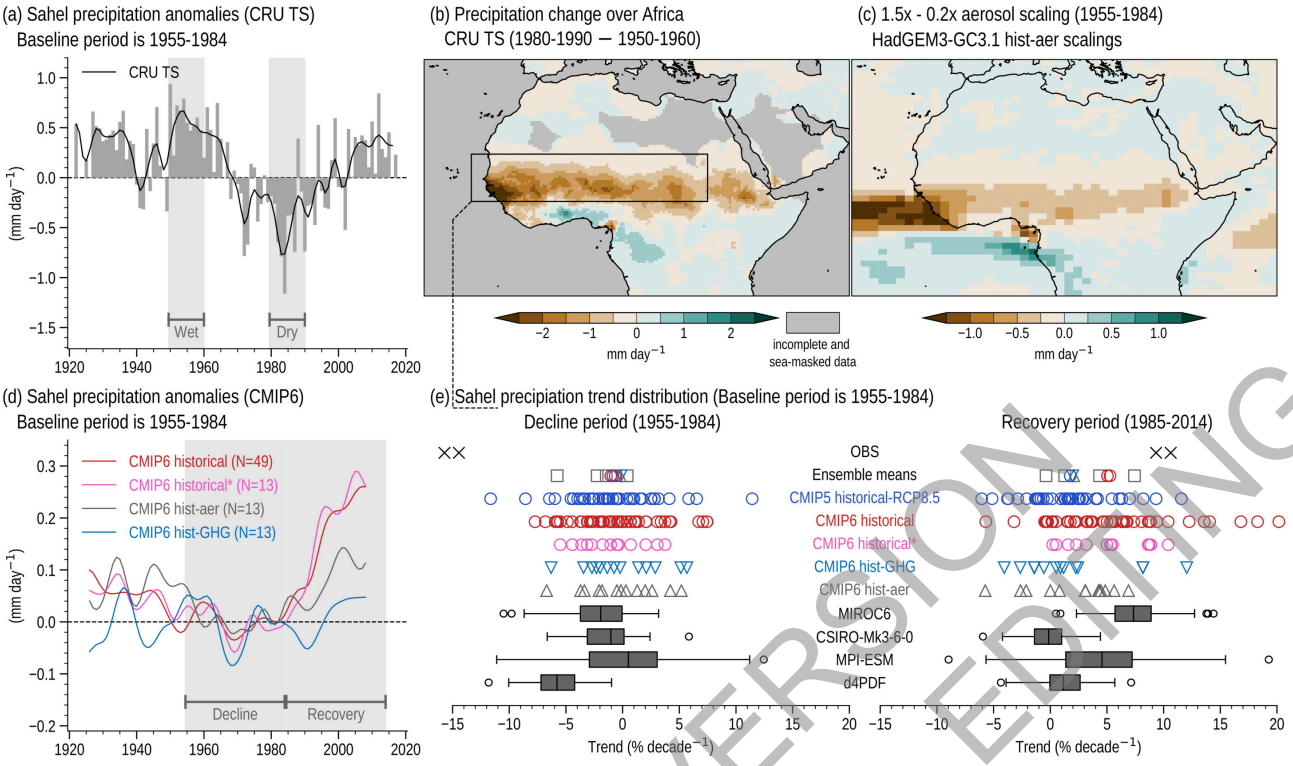

Figure 10.11: Attribution of historic precipitation change in the Sahelian West African monsoon during June to September. (a) Time series of CRU TS precipitation anomalies (mm day^{-1}, baseline 1955–1984) in the Sahel box (10°N–20°N, 20°W–30°E) indicated in panel (b) applying the same low-pass filter as that used in Figure 10.10. The two periods used for difference diagnostics are shown in grey columns. (b) Precipitation change (mm day^{-1}) in CRU TS data for 1980–1990 minus 1950–1960 periods. (c) Precipitation difference (mm day^{-1}) between 1.5x and 0.2x historical aerosol emissions scaling factors averaged over 1955–1984 and five ensemble members of HadGEM3 experiments after Shonk et al. (2020). (d) Sahel precipitation anomaly time series (mm day^{-1}, baseline 1955–1984) in CMIP6 for 49 historical simulations with all forcings (red), and thirteen for each of greenhouse gas-only forcing (light blue) and aerosol-only forcing (grey), with a thirteen-point weighted running mean applied (a variant on the binomial filter with weights [1-6-19-42-71-96-106-96-71-42-19-6-1]). The CMIP6 subsample of all forcings matching the individual forcing simulations is also shown (pink). (e) Precipitation linear trend (% per decade) for (left) decline (1955–1984) and (right) recovery periods (1985–2014) for ensemble means and individual CMIP6 historical experiments (including single-forcing) as in panel (d) plus 34 CMIP5 models (dark blue). Box-and-whisker plots show the trend distribution of the three coupled and the d4PDF atmosphere-only SMILEs used throughout Chapter 10 and follow the methodology used in Figure 10.6. The two black crosses represent observational estimates from GPCC and CRU TS. Trends are estimated using ordinary least-squares regression. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

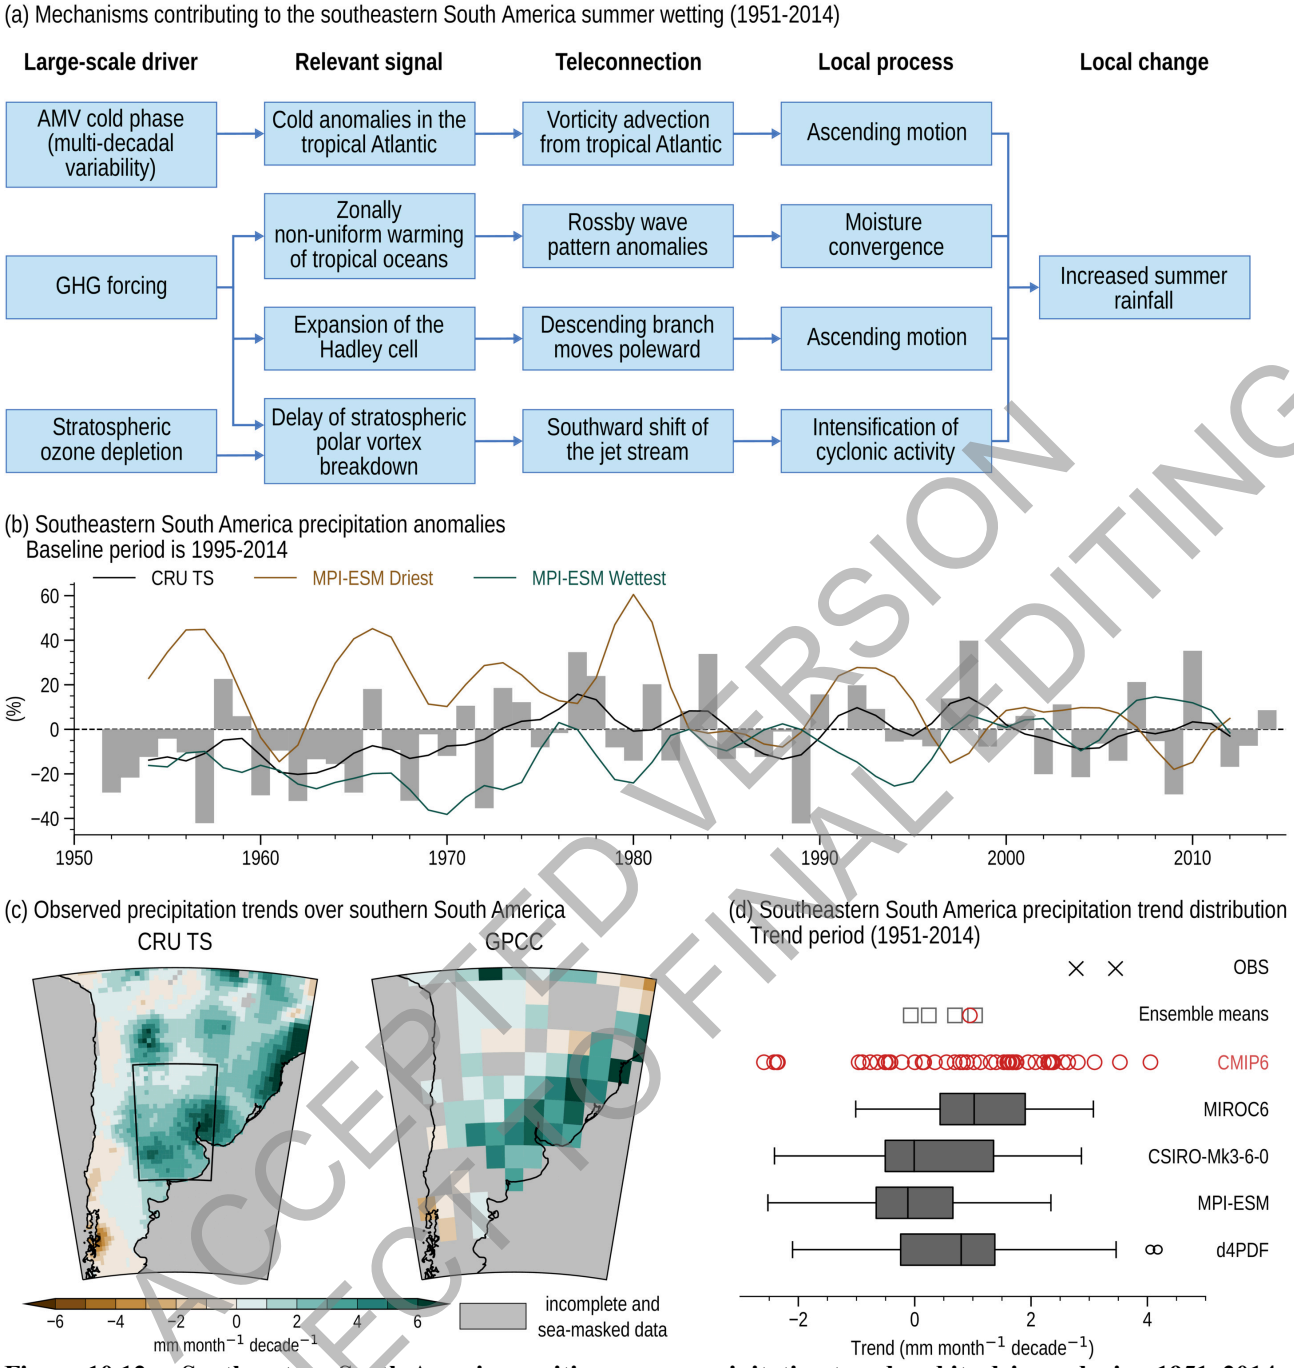

Figure 10.12: **Southeastern South America positive mean precipitation trend and its drivers during 1951–2014.** (a) Mechanisms that have been suggested to contribute to southeastern South America summer wetting. (b) Time series of austral summer (December to February) precipitation anomalies (%, baseline 1995–2014) over the south-eastern South American region (26.25°S–38.75°S, 56.25°W–66.25°W), black quadrilateral in the first map of panel (c). Black, brown and green lines show low-pass filtered time series for CRU TS, and the members with driest and wettest trends of the MPI-ESM SMILE (between 1951–2014), respectively. The filter is the same as the one used in Figure 10.10. (c) Mean austral summer precipitation spatial linear 1951–2014 trends (mm per month and decade) from CRU TS and GPCC. Trends are estimated using ordinary least squares regression. (d) Distribution of precipitation 1951–2014 trends over southeastern South America from GPCC and CRU TS (black crosses), CMIP6 all-forcing historical (red circles) and MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF SMILEs (grey box-and-whisker plots). Grey squares refer to ensemble mean trends of their respective SMILE and the red circle refers to the CMIP6 multi-model mean. Box-and-whisker plots follow the methodology used in Figure 10.6. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

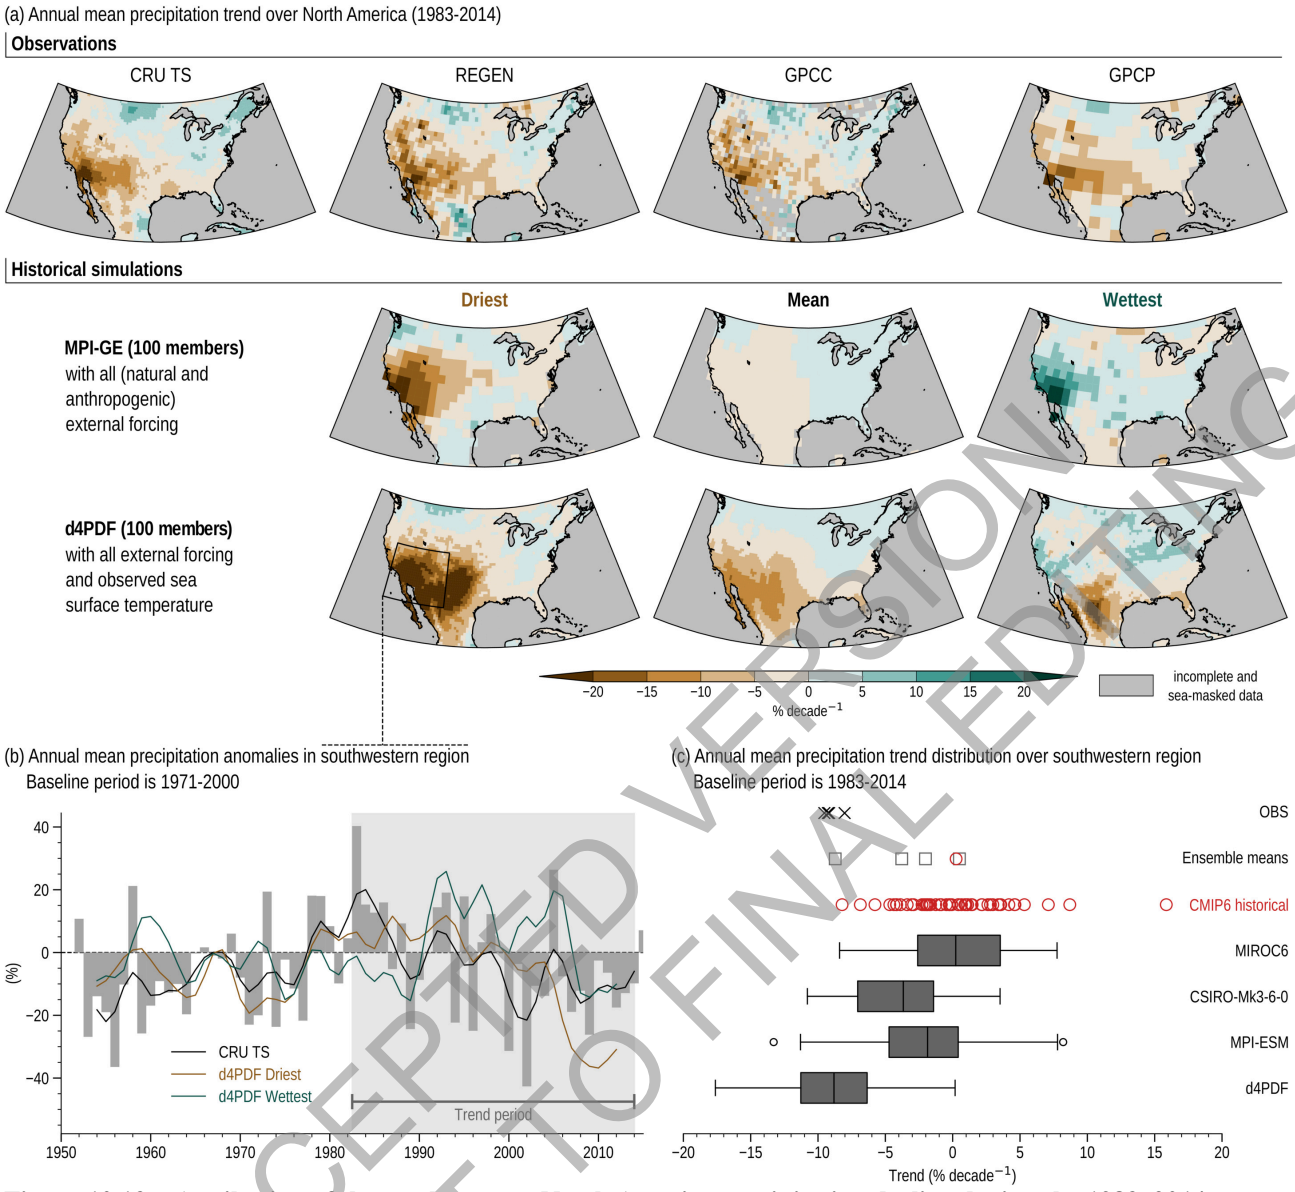

Figure 10.13: Attribution of the southwestern North America precipitation decline during the 1983–2014 period. (a) Water year (October to September) precipitation spatial linear trend (in percent per decade) over North America from 1983 to 2014. Trends are estimated using ordinary least squares. Top row: Observed trends from CRU TS, REGEN, GPCC, and the Global Precipitation Climatology Project (GPCP). Middle row: Driest, mean and wettest trends (relative to the region enclosed in the black quadrilateral, bottom row) from the 100 members of the MPI-ESM coupled SMILE. Bottom row: Driest, mean and wettest trends relative to the above region from the 100 members of the d4PDF atmosphere-only SMILE. (b) Time series of water year precipitation anomalies (%, baseline 1971–2000) over the above south-western North America region for CRU TS (grey bar charts). Black, brown and green lines show low-pass filtered time series for CRU TS, driest and wettest members of the d4PDF SMILE, respectively. The filter is the same as the one used in Figure 10.10. (c) Distribution of south-western region-averaged water-year precipitation 1983–2014 trends (in percent per decade) for observations (CRU TS, REGEN, GPCC and GPCP, black crosses), CMIP6 all-forcing historical simulations (red circles), the MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF SMILEs (grey box-and-whisker plots). Grey squares refer to ensemble mean trends of their respective SMILE and the red circle refers to the CMIP6 multi-model mean. Box-and-whisker plots follow the methodology used in Figure 10.6. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

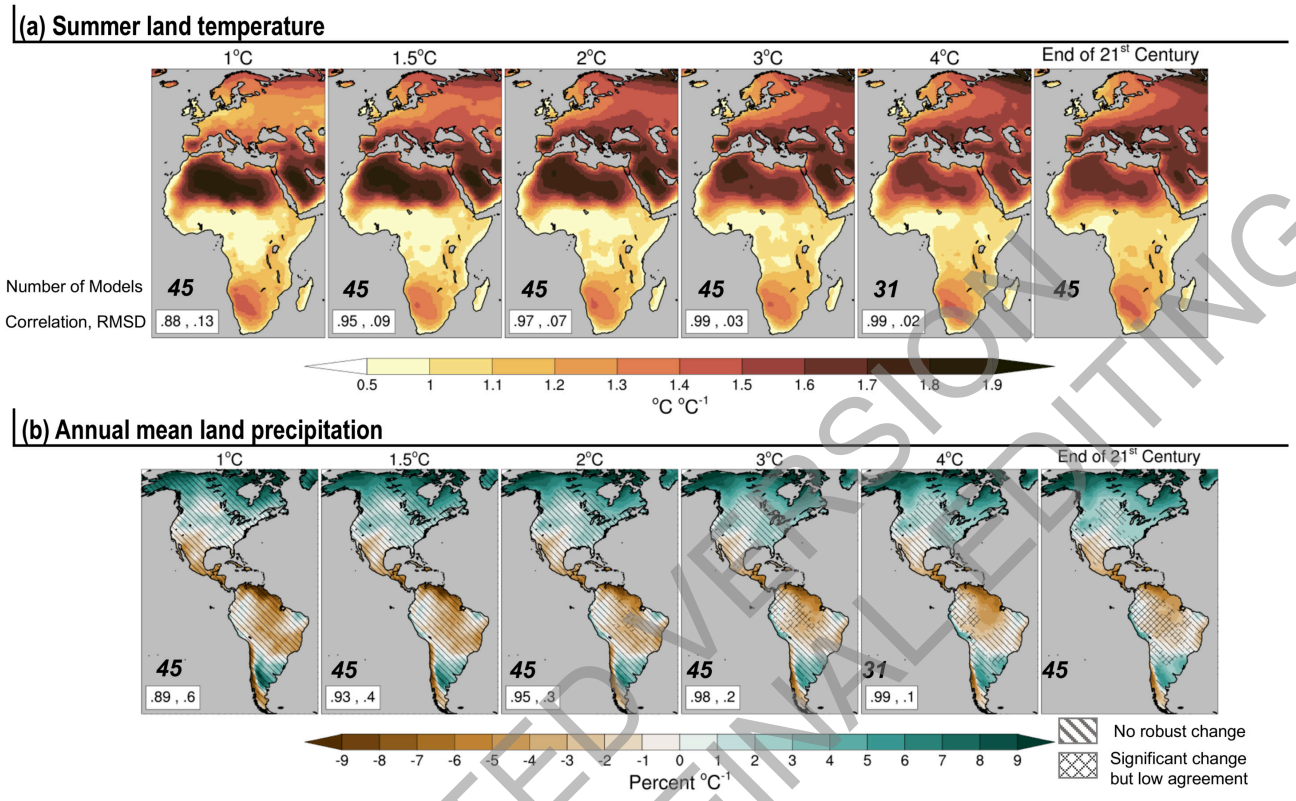

Figure 10.14: Robustness and scalability of anthropogenic signals at regional scale. (a) Spatial patterns of Europe and Africa summer (June to August) surface air temperature change (in °C °C^{-1}) from the CMIP6 multi-model mean (45 models, one member per model, historical simulations and scenario SSP5-8.5) at different global warming levels (GWLs) and the end-21st century scaling pattern estimated from the multi-model mean difference between 2081–2100 and the pre-industrial period (1850–1900) divided by the corresponding global mean warming. The scale of all GWL patterns has been adjusted to a global mean warming of 1°C (for example, the resulting 3°C spatial pattern has been divided by three). The scales of the GWL patterns have to be multiplied by their threshold values to obtain the actual simulated warming. The metrics shown in the bottom left corner of the GWL pattern plots indicate the spatial pattern correlation and the root-mean square difference between the GWL patterns and the scaling pattern. The number in bold just above the metrics gives the number of used CMIP6 models (out of 45) that have reached the GWL threshold. Areas with robust change (at least 66% of the models have a signal to noise ratio greater than one and 80% or more of the models agree on the sign of the change) are coloured with no pattern overlaid (Cross-Chapter Box Atlas.1). Areas with a significant change (at least 66% of the models have a signal to noise ratio greater than one) and lack of model agreement (meaning that less than 80% of the models agree on the sign of the change) are marked by cross-hatching. Areas with no change or no robust change (less than 66% of the models have a signal to noise ratio greater than one) are marked by negatively sloped hatching. (b) Same as (a) but for North, Central and South America annual mean precipitation relative change (percent °C^{-1}). The baseline for precipitation climatology is 1850–1900. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

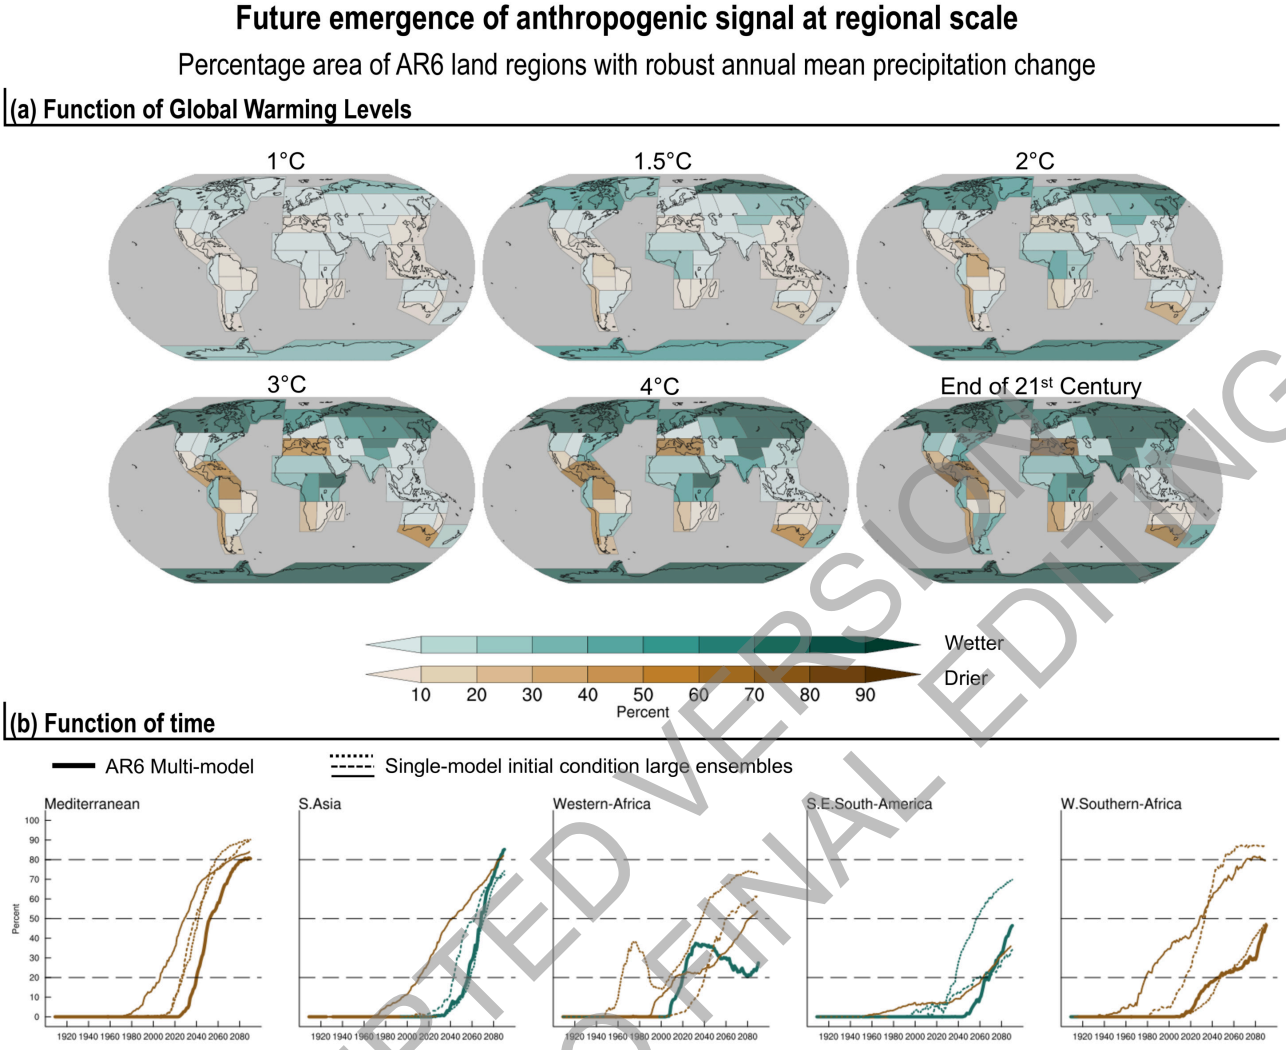

Figure 10.15: Future emergence of anthropogenic signal at regional scale. (a) Percentage area of land regions with robust annual mean precipitation change as a function of increasing GWLs. Robustness of the precipitation change is first estimated at each grid-point followed by the estimation of the AR6 region area with robust changes. For each CMIP6 model considered (45 models, one member per model, historical simulations and scenario SSP5-8.5), the annual mean precipitation change is based on the difference between a 20-year average centred on the GWL crossing year and the mean precipitation during the pre-industrial period (1850–1900) taken as a reference. Robustness of the change is acted when at least 66% of the models (30 out of 45) have a signal to noise ratio greater than one and at least 80% of them (36 out of 45) agree on the sign of change. The signal to noise ratio is estimated for each model from the ratio between the change and the standard deviation of non-overlapping 20-year means of the corresponding pre-industrial simulation (scaled by square root of 2 times 1.645). (b) Time evolution of the percentage area of land region with robust annual mean precipitation change for five AR6 land regions. Thick solid lines represent precipitation changes based on the same CMIP6 ensemble as in (a). Thin solid, dotted and dashed lines represent changes based on the three coupled SMILEs used in Chapter 10, illustrating the influence of internal variability on the emergence of robust change. The change is estimated from the difference between all consecutive 20-year periods from 1900–1919 up to 2081–2100 and the pre-industrial period. The line colour indicates the sign of the robust change given by the multi-model mean (CMIP6) or ensemble mean (SMILE) change: brown (decreasing precipitation) and dark green (increasing precipitation). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

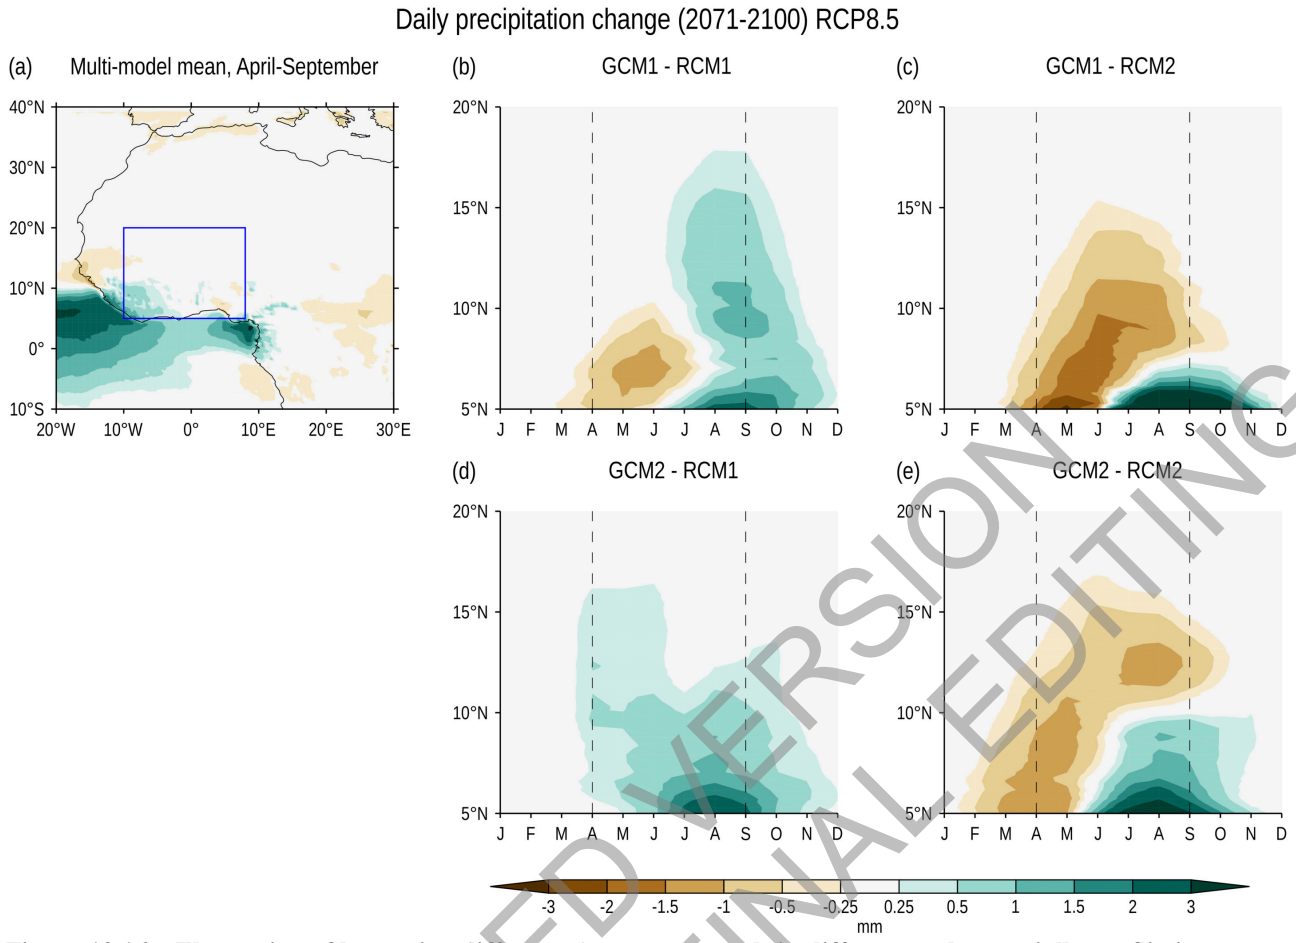

Figure 10.16: Illustration of how using different sources can result in different and potentially conflicting information. Change in daily precipitation (2071–2100 RCP8.5 relative to 1981–2010) over West Africa as simulated by an ensemble of GCM-driven RCMs. (a) Change in daily precipitation (mm) for April to September, as mean of 17 CORDEX models (Dosio et al., 2020) (b-e) Time-latitude diagram of daily precipitation change for four selected RCM-GCM combinations. For each month and latitude, model results are zonally averaged between 10°W–10°E (blue box in a). Different GCM-RCM combinations can produce substantially different and contrasting results, when the same RCM is used to downscale different GCMs (b, d), or the same GCM is downscaled by different RCMs (d, e). GCM1=IPSL-IPSL-CM5A, GCM2=ICHEC-EC-EARTH, RCM1=RCA4, RCM2=REMO2009. Adapted from (Dosio et al., 2020), CCBY4.0 https://creativecommons.org/licenses/by/4.0/. ACCEPTED VERSION SUBJECT TO FINAL EDITING

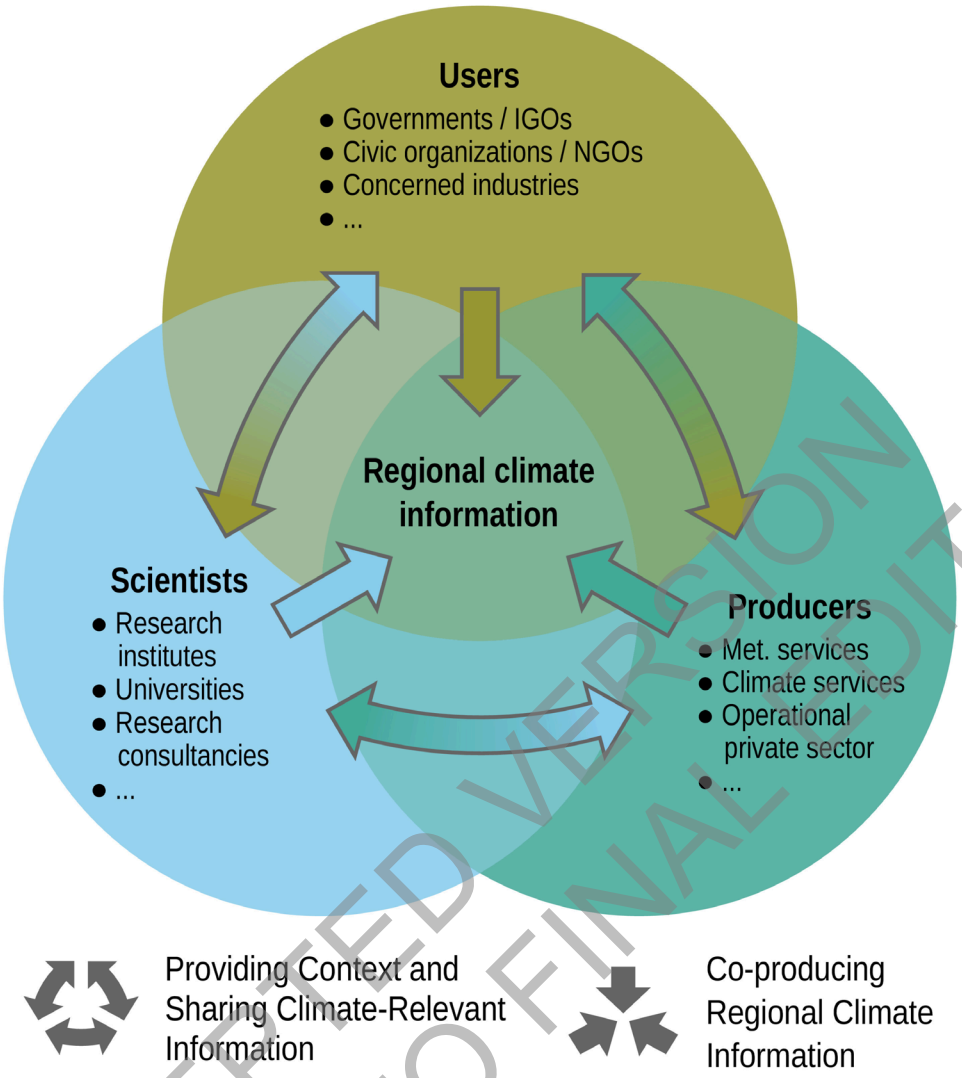

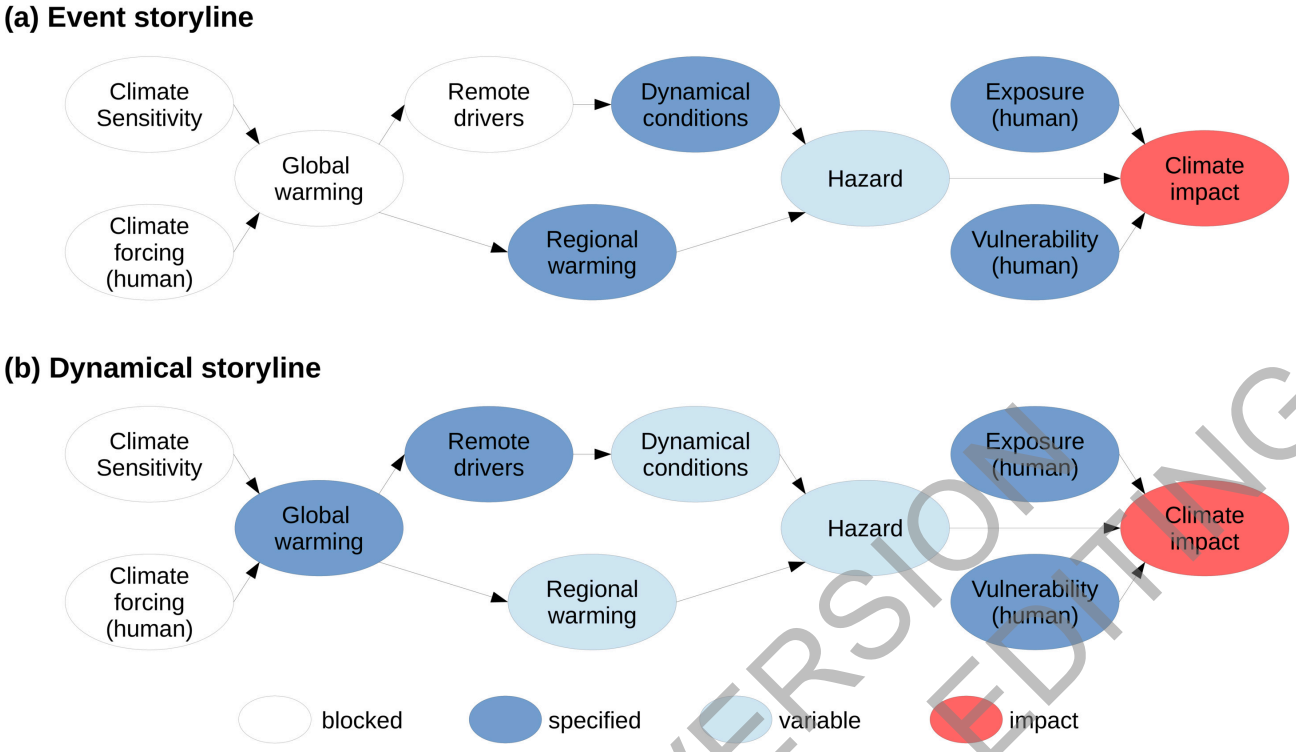

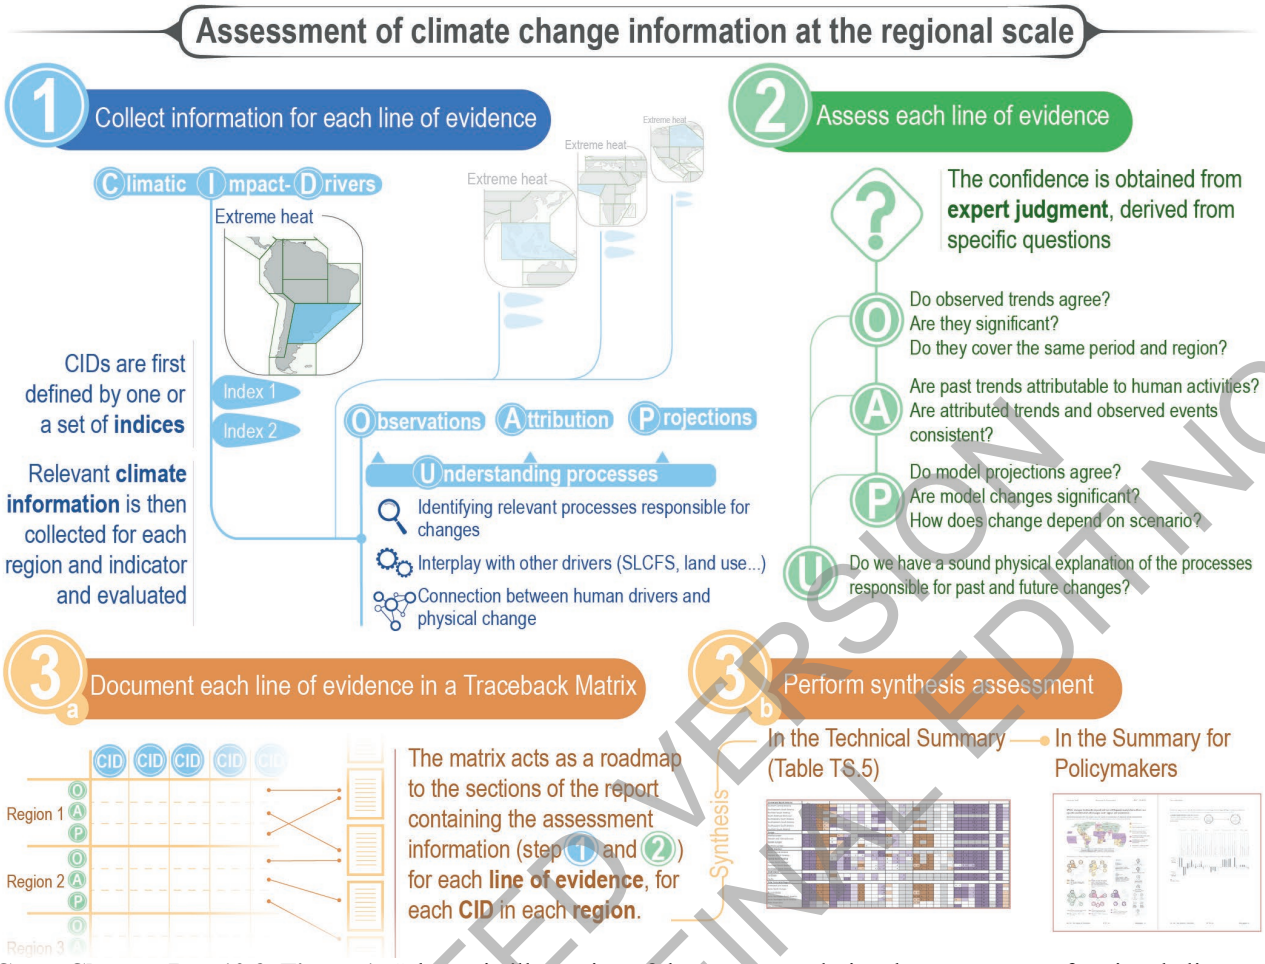

Figure 10.17: Effective regional climate information requires shared development of actionable information that engages all parties involved and the values that guide their engagement. Participants in the development of climate information come from varying perspectives, based in part on their professions and communities. Each of the three broad categories shown in the Venn diagram (Users, Producers, Scientists) is not a homogenous group, and often has a diversity of perspectives, values and interests among its members. The subheadings in each category are illustrative and not all-inclusive. The arrows connecting those categories represent the distillation process of providing context and sharing climate relevant information. The arrows that point toward the centre represent the distillation of climate information that involves all three categories.

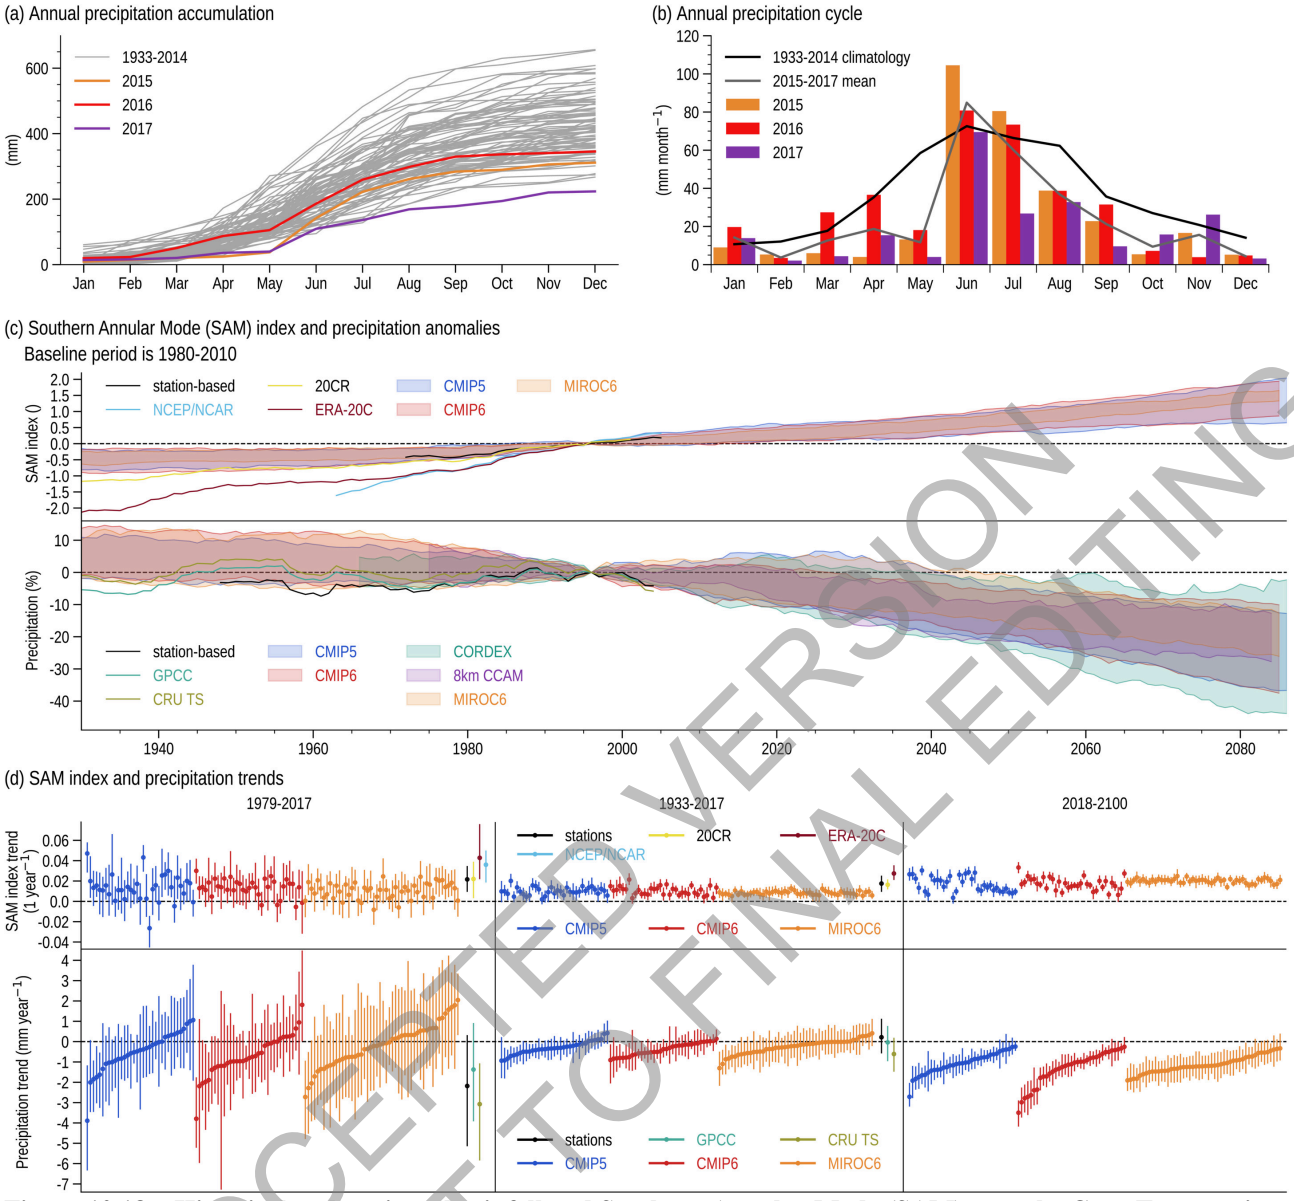
ACCEPTED VERSION SUBJECT TO FINAL EDITING

Box 10.2, Figure 1: Schematic of two types of physical climate storylines with a particular climate impact of concern (red). The storylines are defined by specified elements (dark blue). Variable elements (light blue) are simulated conditional on the specified elements. The white elements are 'blocked' since their state does not need to be known to determine the light blue elements. Other types of storylines could be defined by specifying other elements (e.g., storylines of different climate sensitivities or different representative concentration pathways). (a) Event storyline, where the particular dynamical conditions during the event as well as the regional warming are specified and control the hazard arising from the event. (b) Dynamical storyline, where the global warming level and remote drivers are specified and control the long-term changes in atmospheric dynamics and regional warming. In both storylines, the impact is also conditioned on specified exposure and vulnerability. Adapted from Shepherd (2019).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Cross-Chapter Box 10.3, Figure 1: Schematic illustration of the process to derive the assessment of regional climate change information based on a distillation process of multiple lines of evidence taken from observed trends, attribution of trends or events, climate model projections, and physical understanding.

ACCEPTED VERSION SUBJECT TO FINAL EDITING



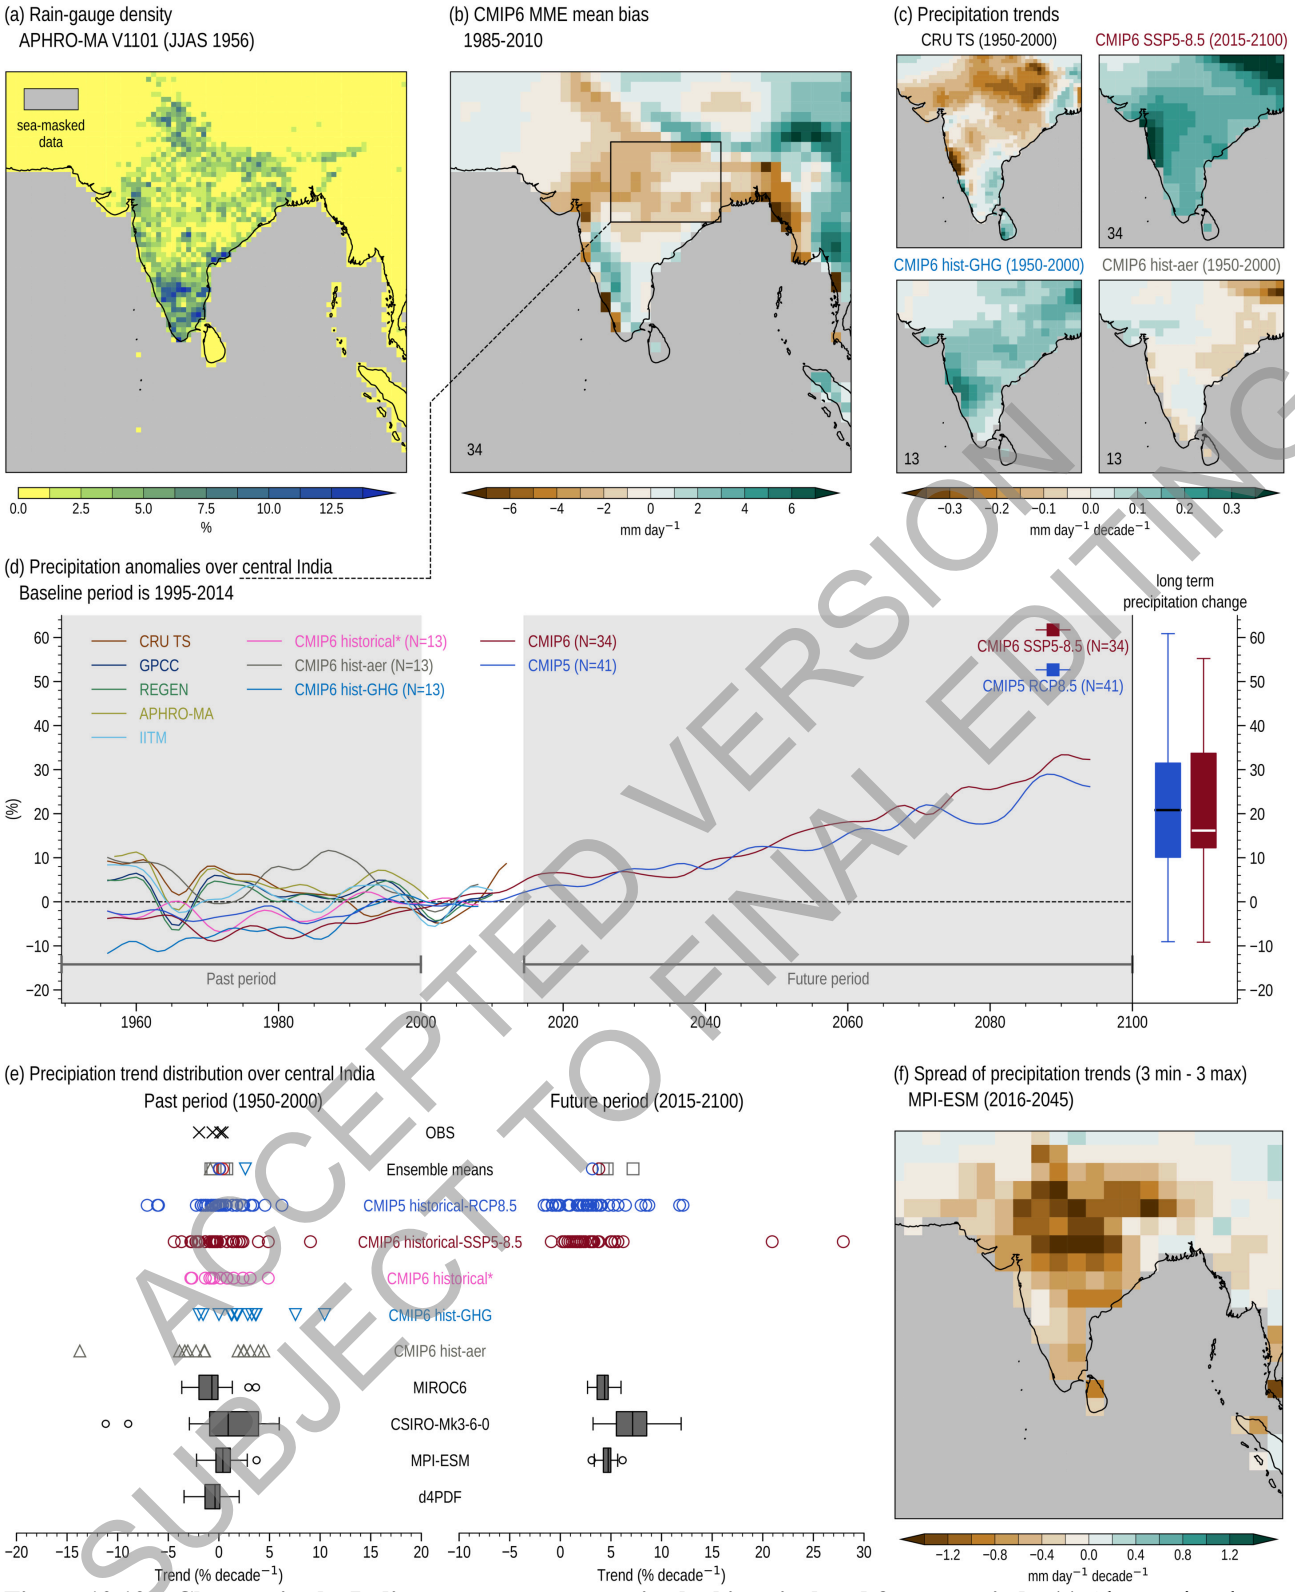


Figure 10.18: **Historical and projected rainfall and Southern Annular Mode (SAM) over the Cape Town region.** (a) Yearly accumulation of rainfall (in mm) obtained by summing monthly totals between January and December, with the drought years 2015 (orange), 2016 (red), and 2017 (purple) highlighted in colour. (b) Monthly rainfall for the drought years (in colour) compared with the 1981–2014 climatology (grey line). Rainfall in (a) and (b) is the average of 20 quality controlled and gap-filled series from stations within the Cape Town region (31ºS–35ºS, 18ºW–20.5ºW). (c) Time series of the SAM index and of historical and projected rainfall anomalies (%, baseline 1980–2010) over the Cape Town region. Observed data presented as 30-year running means of relative total annual rainfall over the Cape Town region for station-based data (black line, average of 20 stations as in (a) and (b)), and gridded data (average of all grid cells falling within 31ºS–35ºS, 18ºW–20.5ºW): GPCC (green line) and CRU TS (olive line). Model ensemble results presented as the 90th-percentile range of relative 30-year running means of rainfall and the SAM index from 35 CMIP5 (blue shading) and 35 CMIP6 (red shading) simulations, 6 CORDEX simulations driven by 1 to 10 GCMs (cyan shading), 6 CCAM (purple shading) simulations from individual ensemble members, and 50 members from the MIROC6 SMILE simulations (orange shading). The light blue, dark red and yellow lines correspond to NCEP/NCAR, ERA20C and 20CR, respectively. The SAM index is calculated from sea-level pressure reanalysis and GCM data as per Gong and Wang (1999) and averaged over the aforementioned bounding box. CMIP5, CORDEX and CCAM projections use RCP8.5, and CMIP6 and MIROC6 SMILE projections use SSP5-8.5. (d) Historical and projected trends in rainfall over the Cape Town region and in the SAM index. Observations and gridded data processed as in (c). Trends calculated as Theil-Sen trend with block-bootstrap confidence interval estimate. Markers show median trend, bars 95% confidence interval. GCMs in each CMIP group were ordered according to the magnitude of trend in rainfall, and

ACCEPTED VERSION SUBJECT TO FINAL EDITING

1 the same order is maintained in panels showing trends in the SAM. Further details on data sources and

Figure 10.19: **Changes in the Indian summer monsoon in the historical and future periods**. (a) Observational uncertainty demonstrated by a snapshot of rain-gauge density (% of 0.05°-subgrid boxes containing at least one gauge) in the APHRO-MA 0.5° daily precipitation dataset for June to September 1956. (b) Multi-model ensemble (MME)-mean bias of 34 CMIP6 models for June to September precipitation (mm day-1) compared to CRU TS observations for the 1985–2010 period. (c) Maps of rainfall trends (mm day-1 per decade) in CRU TS observations (1950–2000), the CMIP6 MME-mean of SSP5-8.5 future projections for 2015–2100 (34 models), the CMIP6 hist-GHG and hist-aer runs, both measured over 1950 to 2000. (d) Low-pass filtered time series of June to September precipitation anomalies (%, relative to 1995–2014 baseline) averaged over the central India box shown in panel (b). The averaging

region (20°N–28°N, 76°E–87°E) follows other works (Bollasina, Ming, & Ramaswamy, 2011; Huang et al., 2020; Jin & Wang, 2017). Time series are shown for CRU TS (brown), GPCC (dark blue), REGEN (green), APHRO-MA (light brown) observational estimates and the IITM all-India rainfall product (light blue) in comparison with the CMIP6 mean of 13 models for the all-forcings historical (pink) the aerosol-only (hist-aer, grey) and greenhouse gas-only (hist-GHG, blue). Dark red and blue lines show low-pass filtered MME-mean change in the CMIP6 historical/SSP5-8.5 (34 models) and CMIP5 historical/RCP8.5 (41 models) experiments for future projections to 2100. The filter is the same as that used in Figure 10.11(d). To the right, box-and-whisker plots show the 2081–2100 change averaged over the CMIP5 (blue) and CMIP6 (dark red) ensembles. Note that some models exceed the plotting range (CMIP5: GISS-E2-R-CC, GISS-E2-R & IPSL-CM5B-LRl and CMIP6: CanESM5-CanOE, CanESM5 & GISS-E2-1-G). (e) Precipitation linear trend (% per decade) over central India for historical 1950–2000 (left) and future 2015–2100 (right) periods in Indian monsoon rainfall in observed estimates (black crosses), the CMIP5 historical-RCP8.5 simulations (blue), the CMIP6 ensemble (dark red) for historical all-forcings experiment and SSP5-8.5 future projection, the CMIP6 hist-GHG (light blue triangles), hist-aer (grey triangles) and historical all-forcings (same sample as for hist-aer and hist-GHG, pink circles). Ensemble means are also shown. Box-and-whisker plots show the trend distribution of the three coupled and the d4PDF atmosphere-only (for past period only) SMILEs used throughout Chapter 10 and follow the methodology used in Figure 10.6. (f) Example spread of trends (mm day^{-1} per decade) out to the near term (2016–2045) in RCP8.5 SMILE experiments of the MPI-ESM model, showing the difference between the three driest and three wettest trends among ensemble members over central India. All trends are estimated using ordinary least-squares regression. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

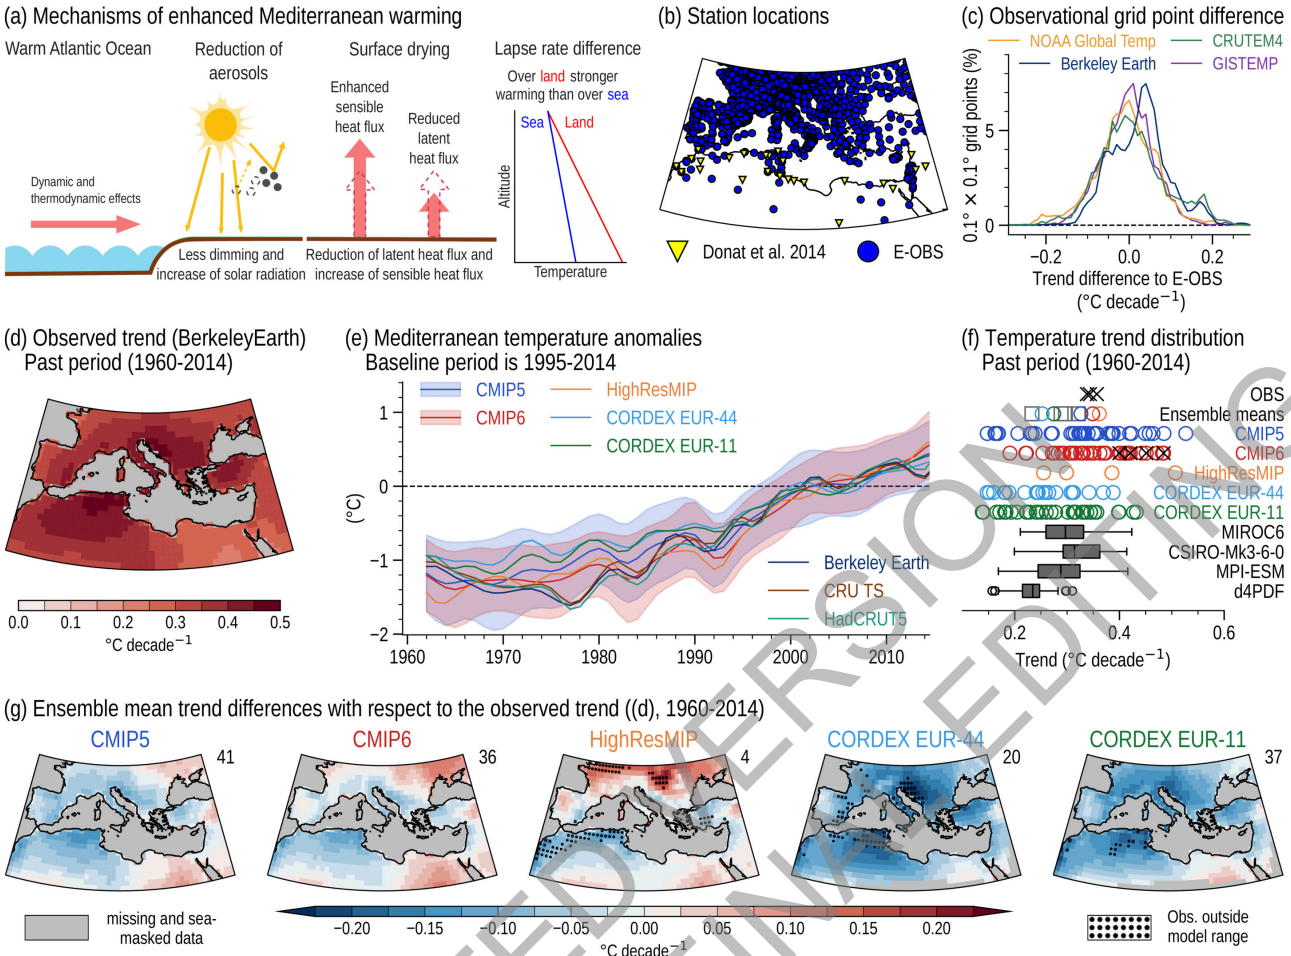

Figure 10.20: Aspects of Mediterranean summer warming. (a) Mechanisms and feedbacks involved in enhanced Mediterranean summer warming. (b) Locations of observing stations in E-OBS and (Donat et al., 2014). (c) Differences in temperature observational data sets (NOAA Global Temp, Berkeley Earth, CRUTEM4 and GISTEMP) with respect to E-OBS for the land points between the Mediterranean Sea and 46°N and west of 30°E. (d) Observed summer (June to August) surface air temperature linear trends (°C decade^{-1}) over the 1960–2014 period from Berkeley Earth. (e) Time series of area averaged Mediterranean (25°N–50°N, 10°W–40°E) land point summer temperature anomalies (°C, baseline 1995–2014). Dark blue, brown and turquoise lines show low-pass filtered temperature of Berkeley Earth, CRU TS and HadCRUT5, respectively. Orange, light blue and green lines show low-pass filtered ensemble means of HighResMIP (4 members), CORDEX EUR-44 (20 members) and CORDEX EUR-11 (37 members). Blue and red lines and shadings show low-pass filtered ensemble means and standard deviations of CMIP5 (41 members) and CMIP6 (36 members). The filter is the same as the one used in Figure 10.10. (f) Distribution of 1960–2014 Mediterranean summer temperature linear trends (°C decade^{-1}) for observations (black crosses), CORDEX EUR-11 (green circles), CORDEX EUR-44 (light blue circles), HighResMIP (orange circles), CMIP6 (red circles), CMIP5 (blue circles) and selected SMILEs (grey box-and-whisker plots, MIROC6, CSIRO-Mk3-6-0, MPI-ESM and d4PDF). Ensemble means are also shown. CMIP6 models showing a very high ECS (Box. 4.1) have been marked with a black cross. All trends are estimated using ordinary least-squares and box-and-whisker plots follow the methodology used in Figure 10.6. (g) Ensemble mean differences with respect to the Berkeley Earth linear trend for 1960–2014 (°C decade^{-1}) of CMIP5, CMIP6, HighResMIP, CORDEX EUR-44 and CORDEX EUR-11. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

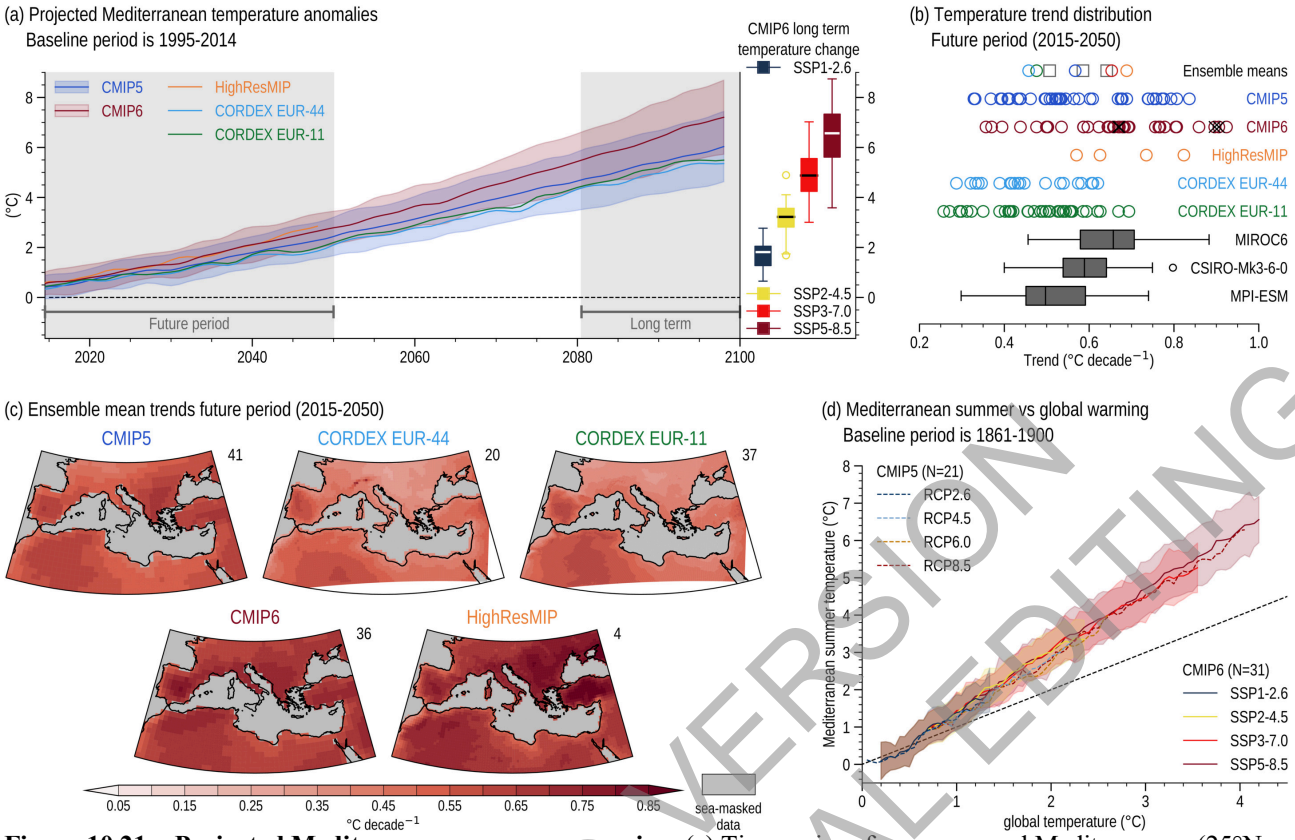

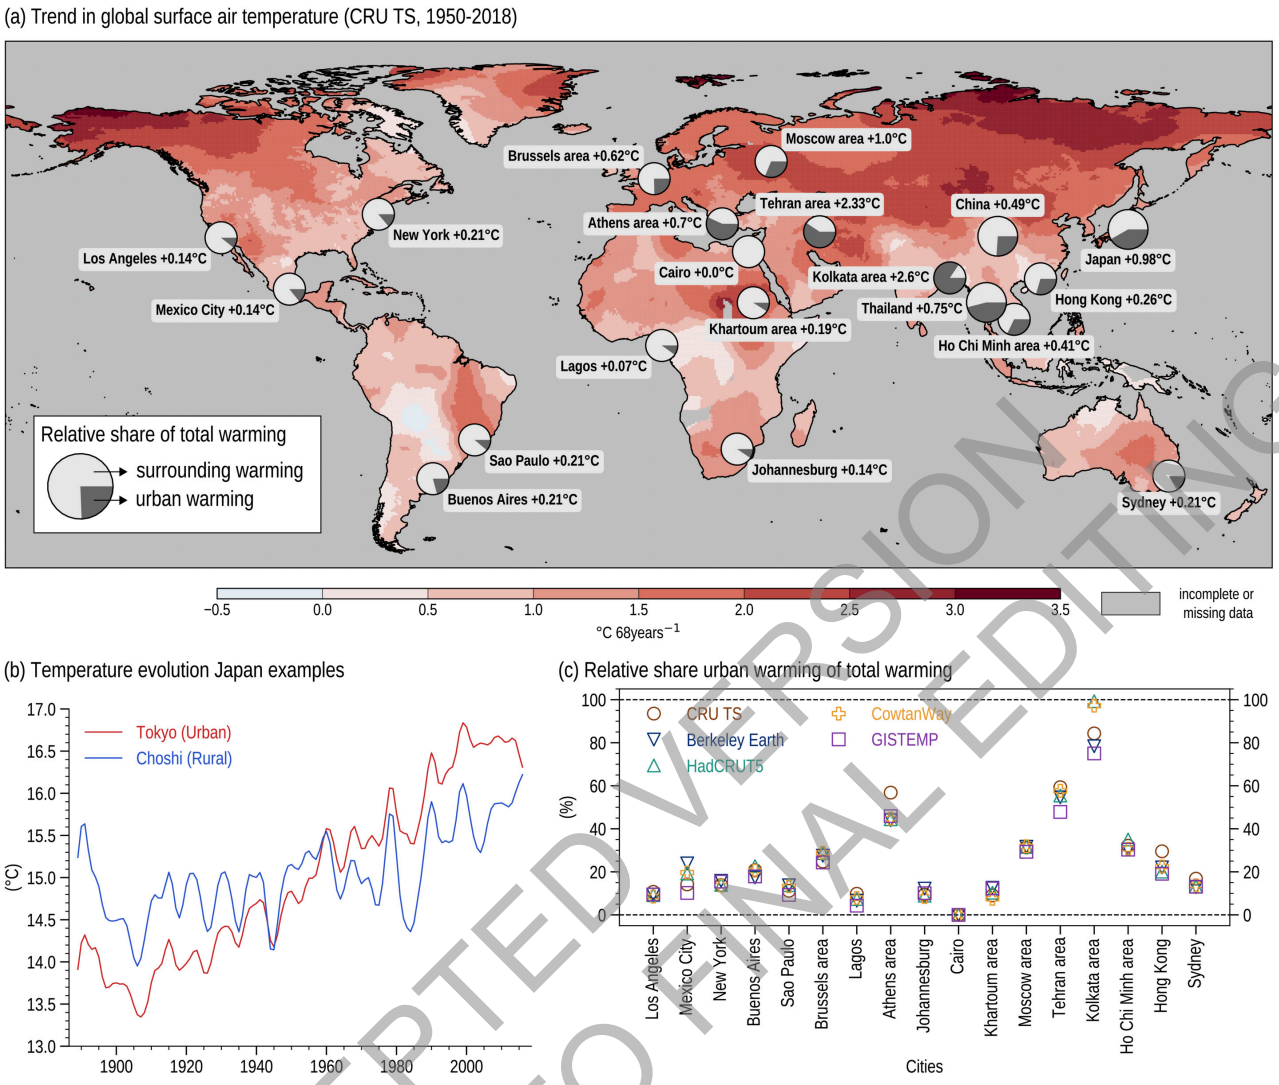

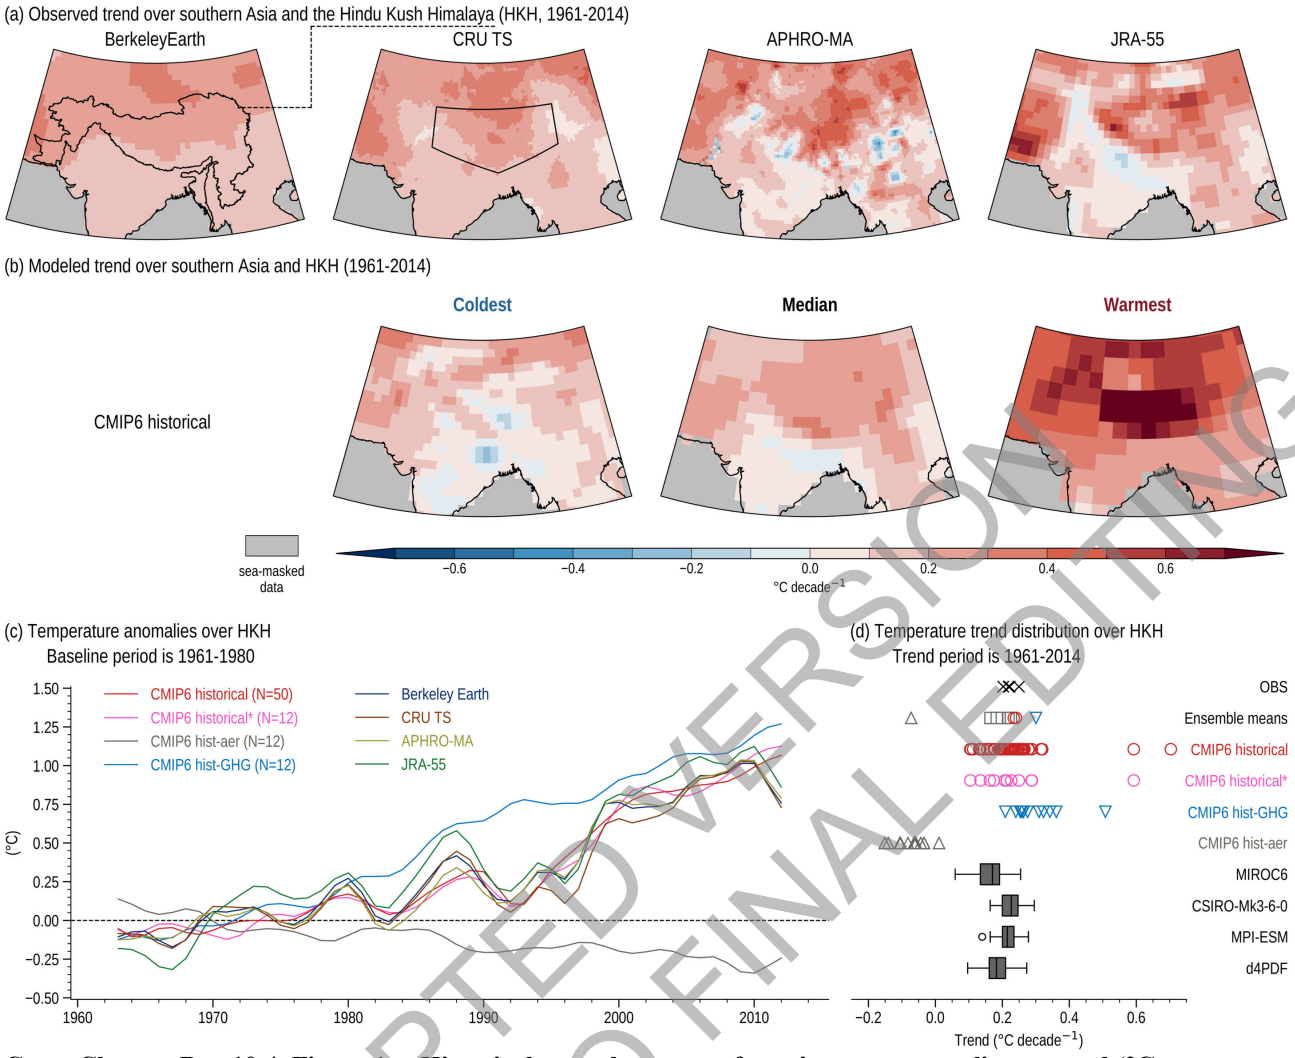

Figure 10.21: Projected Mediterranean summer warming. (a) Time series of area averaged Mediterranean (25°N–50°N, 10°W–40°E) land point summer surface air temperature anomalies (°C, baseline period is 1995–2014). Orange, light blue and green lines show low-pass filtered ensemble means of HighResMIP (highres-future, 4 members), CORDEX EUR-44 (RCP8.5, 20 members) and CORDEX EUR-11 (RCP8.5, 37 members). Blue and dark red lines and shadings show low-pass filtered ensemble means and standard deviations of CMIP5 (RCP8.5, 41 members) and CMIP6 (SSP5-8.5, 36 members). The filter is the same as the one used in Figure 10.10. The box-and-whisker plots show long term (until 2081-2100) temperature changes of different CMIP6 scenarios with respect to the baseline period (SSP1-2.6 in dark blue, SSP2-4.5 in yellow, SSP3-7.0 in red, SSP5-8.5 in dark red). (b) Distribution of 2015–2050 Mediterranean summer temperature linear trends (°C decade^{-1}) for CORDEX EUR-11 (RCP8.5, green circles), CORDEX EUR-44 (RCP8.5, light blue circles), HighResMIP (highres-future, orange circles), CMIP6 (SSP5-8.5, dark red circles), CMIP5 (RCP8.5, blue circles) and selected SMILEs (grey box-and-whisker plots, MIROC6, CSIRO-Mk3-6-0 and MPI-ESM). Ensemble means are also shown. CMIP6 models showing a very high ECS (Box 4.1) have been marked with a black cross. All trends are estimated using ordinary least-squares and box-and-whisker plots follow the methodology used in Figure 10.6. (c) Projections of ensemble mean 2015–2050 linear trends (°C decade^{-1}) of CMIP5 (RCP8.5), CORDEX EUR-44 (RCP8.5), CORDEX EUR-11 (RCP8.5), CMIP6 (SSP5-8.5) and HighResMIP (highres-future). All trends are estimated using ordinary least-squares. (d) Projected Mediterranean summer warming in comparison to global annual mean warming of CMIP5 (dashed lines, RCP2.6 in dark blue, RCP4.5 in light blue, RCP6.0 in orange and RCP8.5 in red) and CMIP6 (solid lines, SSP1-2.6 in dark blue, SSP2-4.5 in yellow, SSP3-7.0 in red and SSP5-8.5 in dark red) ensemble means. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

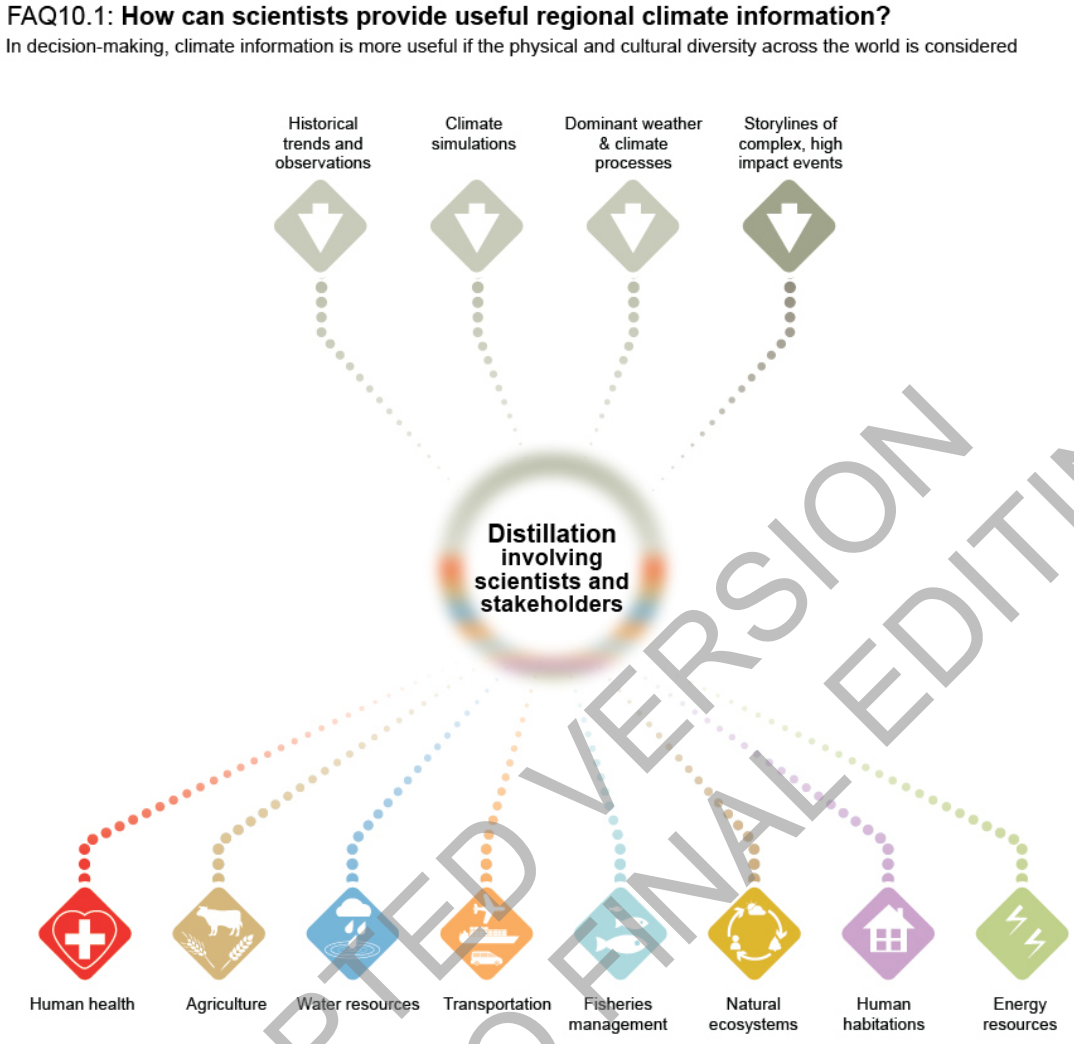
SUBJECT TO FINAL EDITING ACCEPTED VERSION



Box 10.3, Figure 1: **Urban warming compared to global GHG-induced warming.** (a) Change in the annual mean surface air temperature over the period 1950–2018 based on the local linear trend retrieved from CRU TS (°C per 68 years). This background warming is compared to the local warming that has been reported during 1950–2018 in the literature from historical urbanization. The relative share of the total warming as percentage between the urban warming and the surrounding warming is plotted in a circle for each city. This map has been compiled from a review study (Hamdi et al., 2020). (b) Low-pass filtered time series of the annual mean temperature (°C) observed in the urban station of Tokyo (red line) and the rural reference station in Choshi (blue line) in Japan. The filter is the same as the one used in Figure 10.10. (c) Uncertainties in the relative share of urban warming with respect to the total warming (%) related to the use of different global observational datasets: CRU TS (brown circles), Berkeley Earth (dark blue downward triangle), HadCRUT5 (cyan upward triangle), Cowtan Way (orange plus) and GISTEMP (purple squares). Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

ACCEPTED VERSION SUBJECT TO FINAL EDITING

Cross-Chapter Box 10.4, Figure 1: Historical annual-mean surface air temperature linear trend (°C per decade) and its attribution over the Hindu Kush Himalaya (HKH) region. (a) Observed trends from Berkeley Earth (also showing the HKH outline), CRU TS (also showing the AR6 TIB outline, for ease of comparison to the Interactive Atlas), APHRO-MA and JRA-55 datasets over 1961–2014. (b) Models showing the coldest, median and warmest HKH temperature linear trends among the CMIP6 historical ensemble over 1961–2014. (c) Lowpass-filtered time series of annual-mean surface air temperature anomalies (°C, baseline 1961–1980) over the HKH region as outlined in panel (a), showing means of CMIP6 hist all-forcings (red), and the CMIP6 hist all-forcings sample corresponding to DAMIP experiments (pink), for hist-aer (grey) and hist-GHG (pale blue). Observed datasets are Berkeley Earth (dark blue), CRU (brown), APHRO-MA (light green) and JRA-55 (dark green). The filter is the same as that used in Figure 10.10. (d) Distribution of annual mean surface air temperature trends (°C per decade) over the HKH region from 1961 to 2014 for ensemble means, the aforementioned observed and reanalysis data (black crosses), individual members of CMIP6 hist all-forcings (red circles), CMIP6 hist-GHG (blue triangles), CMIP6 hist-aer (grey triangles), and box-and-whisker plots for the SMILEs used throughout Chapter 10 (grey shading). Ensemble means are also shown. All trends are estimated using ordinary least-squares regression and box-and-whisker plots follow the methodology used in Figure 10.6. Further details on data sources and processing are available in the chapter data table (Table 10.SM.11).

FAQ 10.1, Figure 1: **Climate information for decision makers is more useful if the physical and cultural diversity across the world is considered.** The figure illustrates schematically the broad range of knowledge that must be blended with the diversity of users to distil information that will have relevance and credibility. This blending or distillation should engage the values and knowledge of both the stakeholders and the scientists. The bottom row contains examples of stakeholders' interests and is not all-inclusive. As part of the distillation, the outcomes can advance the U.N.'s Sustainable Development Goals, covered in part by these examples.

FAQ 10.2: **Why are cities the hotspots of global warming?**

Cities are usually warmer than their surrounding areas due to factors that trap and release heat and a lack of natural cooling influences, such as water and vegetation.

FAQ 10.1, Figure 2: Efficiency of the various factors at warming up or cooling down neighbourhoods of urban areas. Overall, cities tend to be warmer than their surroundings. This is called the 'urban heat island' effect. The hatched areas on the bars show how the strength of the warming or cooling effects of each factor varies depending on the local climate. For example, vegetation has a stronger cooling effect in temperate and warm climates. Further details on data sources are available in the chapter data table (Table 10.SM.11).

10.SM.1 Regional Traceback Matrices

[START TABLE 10.SM.1 HERE]

Table 10.SM.1: Regional Traceback Matrix for Africa. Table shows chapter traceability of the regional assessment using observed trends, attribution of trends or events, and climate model projections, as described in Cross-Chapter Box 10.3. The Table is divided into separate panels that correspond to the WGI AR6 Reference Regions. African sub-regions are: Panel A: (Mediterranean) North Africa (MED), Panel B: Sahara (SAH), Panel C: West-Africa (WAF), Panel D: Central-Africa (CAF), Panel E: N.Eastern-Africa (NEAF), Panel F: S.Eastern-Africa (SEAF), Panel G: W.Southern-Africa (WSAF), Panel H: E.Southern-Africa (ESAF), Panel I: Madagascar (MDG). Blank cells in the observations and projections columns corresponding to the "not broadly relevant" or "no evidence" category as described in the CID framework in Chapter 12. Blank cells in the detection and attribution columns correspond to no studies being available.

[START TABLE 10.SM.2 HERE]

Table 10.SM.2: Regional Traceback Matrix for Asia. Table shows chapter traceability of the regional assessment using observed trends, attribution of trends or events, and climate model projections, as described in Cross-Chapter Box 10.3. The Table is divided into separate panels that correspond to the WGI AR6 Reference Regions. African sub-regions are: Panel A: E.Asia (EAS), Panel B: E.C.Asia (ECA), Panel C: Tibetan-Plateau (TIB), Panel D: S.Asia (SAS), Panel E: S.E.Asia (SEA), Panel F: Arabian-Peninsula (ARP), Panel G: W.C.Asia (WCA), Panel H: W.Siberia (WSB), Panel I: E.Siberia (ESB), Panel J: Russian-Far-East (RFE). Blank cells in the observations and projections columns corresponding to the "not broadly relevant" or "no evidence" category as described in the CID framework in Chapter 12. Blank cells in the detection and attribution columns correspond to no studies being available.

[START TABLE 10.SM.3 HERE]

Table 10.SM.3: Regional Traceback Matrix for Australasia. Table shows chapter traceability of the regional assessment using observed trends, attribution of trends or events, and climate model projections, as described in Cross-Chapter Box 10.3. The Table is divided into separate panels that correspond to the WGI AR6 Reference Regions. African sub-regions are: Panel A: N.Australia (NAU), Panel B: C.Australia (CAU), Panel C: E.Australia (EAU), Panel D: S.Australia (SAU), Panel E: New-Zealand (NZ). Blank cells in the observations and projections columns corresponding to the "not broadly relevant" or "no evidence" category as described in the CID framework in Chapter 12. Blank cells in the detection and attribution columns correspond to no studies being available.

[START TABLE 10.SM.4 HERE]

Table 10.SM.4: Regional Traceback Matrix for Central America. Table shows chapter traceability of the regional assessment using observed trends, attribution of trends or events, and climate model projections, as described in Cross-Chapter Box 10.3. The Table is divided into separate panels that correspond to the WGI AR6 Reference Regions. African sub-regions are: Panel A: S.Central-America (SCA), Panel B: N.Central-America (NCA). Blank cells in the observations and projections columns corresponding to the "not broadly relevant" or "no evidence" category as described in the CID framework in Chapter 12. Blank cells in the detection and attribution columns correspond to no studies being available.

[START TABLE 10.SM.8 HERE]

Table 10.SM.8: Regional Traceback Matrix for Polar. Table shows chapter traceability of the regional assessment using observed trends, attribution of trends or events, and climate model projections, as described in Cross-Chapter Box 10.3. The Table is divided into separate panels that correspond to the WGI AR6 Reference Regions. African sub-regions are: Panel A: Russian-Arctic (RAR), Panel B: Greenland/Iceland (GIC), Panel C: Arctic N.W.North-America (aNWN), Panel D: Arctic N.E.North-America (aNEN), Panel E: Arctic N.Europe (aNEU), Panel F: E.Antarctica (EAN), Panel G: W.Antarctica (WAN). Blank cells in the observations and projections columns corresponding to the "not broadly relevant" or "no evidence" category as described in the CID framework in Chapter 12. Blank cells in the detection and attribution columns correspond to no studies being available.

Table 10.SM.9: Regional Traceback Matrix for Small Islands. Table shows chapter traceability of the regional assessment using observed trends, attribution of trends or events, and climate model projections, as described in Cross-Chapter Box 10.3. The Table is divided into separate panels that correspond to the WGI AR6 Reference Regions. African sub-regions are: Panel A: Caribbean (CAR), Panel B: Pacific Islands (EPO/SPO), Panel C: Western Indian Ocean Islands (EIO/SIO). Blank cells in the observations and projections columns corresponding to the "not broadly relevant" or "no evidence" category as described in the CID framework in Chapter 12. Blank cells in the detection and attribution columns correspond to no studies being available.
